Editor's Corner

The Editor's Corner *provides perspective from the Editor in Chief on critical topics for systems engineering, either through their own words or by inviting a guest writer.*

11 November 2025

Together, We Shape the SEBoK

At a recent conference of the American Society for Engineering Management (ASEM), I had one of those moments that reminds me why I love the systems engineering community. Between sessions, I struck up a conversation with a few attendees and quickly discovered that ASEM has its own body of knowledge. As we compared notes, I realized how much overlap exists between our work in systems and engineering management as well as how rarely we stop to connect those dots. Even more surprising was that several INCOSE colleagues I know well were there, simply wearing a different "hat." One new conference friend and I joked that we had each found a new "conference bestie" in the most unexpected of places. That small moment of discovery captured something that sits at the heart of the SEBoK: collaboration.

The SEBoK isn't just a collection of articles. It's a community space — a shared effort built by and for the global systems engineering ecosystem. Our strength lies in the ways people and organizations come together around it.

The Power of Partnership

From the beginning, the SEBoK has been sustained by partnership. In 2009, when BKCASE – the parent project that kicked off the SEBoK – was created, Art Pyster and David Olwell brought together over 70 authors representing government, industry, and academia from around the world,. It was only through this incredibly diverse group, and Art and Dave's leadership, that the SEBoK was able to become what it is today: an authoritative, evolving body of knowledge that reflects the diversity of our global systems community.

The three steward organizations – International Council on Systems Engineering (INCOSE), the IEEE Systems Council (previously the Computer Society), and the Stevens Institute of Technology's Systems Engineering Research Center (SERC) – each bring unique perspectives and strengths. Together, they ensure the SEBoK continues to evolve as both an authoritative reference and a bridge across disciplines. This multi-institution collaboration is part of what makes the SEBoK so distinctive: no single organization could achieve the same reach or relevance alone. That spirit of cooperation extends far beyond our stewards. Over the past year, several SEBoK editorial board members have played key roles in aligning updates across related efforts, most notably the *INCOSE Systems Engineering Handbook v. 5.0* and the new version of *ISO/IEC/IEEE 15288*. These efforts have brought the systems community into closer alignment, helping practitioners speak a more common language. Special thanks go to David Endler, Garry Roedler, and Mike Yokell for their leadership in this space. Our Lead Editor for Part 6, Caitlyn Singam, continues to champion collaboration with other professional societies through both her work on the SEBoK and the SySTEAM initiative. Judith Dahmann and Michael Henshaw bring the knowledge and activities of the

INCOSE Systems of Systems (SoS) Working Group (WG) forward into the SEBoK. Gary Smith, lead editor of Part 2, is also the current President of the International Society for the Systems Sciences (ISSS). Javier Calvo-Amodio – incidentally one of the colleagues I got to see at ASEM – is also very engaged in the systems science community. Former editor Phyllis Marbach has supported coordination between the International Association for the Engineering Modelling, Analysis & Simulation (NAFEMS) and the SEBoK for modeling and simulation terminology.

I won't try to create an exhaustive list of the ways in which our authors, editors, and stewards have supported and embraced cross collaboration with other professional societies and disciplines – I would be sure to leave someone or some collaboration out. But these examples help to demonstrate how the broader community has come together to build the SEBoK and, I hope, how the SEBoK represents an avenue to bring the community together.

SEBoK's collaborative ecosystem reaches well beyond standards. It connects to other bodies of knowledge and communities of practice — whether in engineering management, software systems, or emerging areas like digital engineering and AI. These intersections strengthen the SEBoK, ensuring that it remains relevant in a rapidly evolving landscape.

The SEBoK's foundation in the BKCASE initiative set the stage for this kind of openness. Over time, our community has embraced that legacy by continuously building connections: to competency frameworks, to digital transformation initiatives, and to the growing body of knowledge on systems engineering for AI-enabled systems. Each of these relationships brings fresh insights and helps us reflect the realities of modern systems practice.

At its core, **collaboration is about people**. It happens in meetings and working groups, but also in the informal spaces — hallway conversations, virtual whiteboards, and chance encounters at conferences. Every relationship built across disciplines or organizations strengthens our collective ability to advance the field.

What I find most inspiring is how naturally collaboration emerges when systems engineers get together. Whether we're debating terminology, aligning frameworks, or brainstorming new ways to teach the next generation, our shared curiosity and systems thinking mindset draw us toward connection. Those relationships are what keep the SEBoK vibrant and alive.

Looking Ahead

As we close out 2025, our focus is turning toward the future. In December, we'll be sharing the **SEBoK Together** initiative – an open invitation for the entire community to help shape what comes next. This effort will guide our work over the next year as we continue to modernize the SEBoK's content, structure, and integration with the broader systems engineering ecosystem featuring weekly opportunities for engagement. Whether you contribute new material, provide feedback, or simply share how you use the SEBoK in your organization, your participation matters. Collaboration has always been the SEBoK's greatest strength. Together, we can ensure that it remains not just a guide to systems engineering knowledge, but a living example of what collaboration can achieve.

Sincerely,

Governance and Editorial Boards

BKCASE Governing Board

The three SEBoK steward organizations – the International Council on Systems Engineering (INCOSE), the Institute of Electrical and Electronics Engineers Systems Council (IEEE-SYSC), and Stevens Institute of Technology – provide the primary funding and resources needed to sustain and evolve the SEBoK and make it available as a free and open resource to all. The stewards appoint the BKCASE Governing Board to be their primary agents to oversee and guide the SEBoK. The stewards appoint the SEBoK Editor in Chief to manage the SEBoK and oversee the Editorial Board.

The BKCASE Governing Board includes:

- Representing the **The International Council on Systems Engineering (INCOSE)**
  - Art Pyster (Governing Board Chair), Emma Sparks
- Representing the **Systems Engineering Research Center (SERC)**
  - Thomas McDermott, Cihan Dagli
- Representing the **IEEE Systems Council (IEEE-SYSC)**
  - Andy Chen (President of IEEE Systems Council), Steve Li (Treasurer of IEEE Systems Council)

Past governors include Stephanie White, Bob Rassa, Richard Fairley, Kevin Forsberg, Paul Frenz, Richard Hilliard, John Keppler, Bill Miller, David Newbern, Ken Nidiffer, Dave Olwell, Massood Towhidnejad, Jon Wade, David Walden, and Courtney Wright. The governors would especially like to acknowledge Andy Chen and Rich Hilliard, IEEE Computer Society, who were instrumental in helping the governors to work within the IEEE CS structure and who supported the SEBoK transition to the IEEE Systems Council. Andy Chen has returned to his governor role after several years off, this time representing the IEEE Systems Council.

Editorial Board

The SEBoK Editorial Board is chaired by the *Editor in Chief*, who provides the strategic vision for the SEBoK. The EIC is supported by a group of Editors, each of whom are responsible for a specific aspect of the SEBoK. The EIC and Editorial Board are supported by the Managing Editor, who handles all day-to-day operations. The EIC, Managing Editor, and Editorial Board are supported by a Student Editor, Eleni Canez, whose hard work and dedication are greatly appreciated.

SEBoK Editor in Chief

Nicole Hutchison

Virginia Tech National Security Institute

nicole.hutchison@stevens.edu [1] or emtnicole@gmail.com [2]

Responsible for the appointment of SEBoK Editors and for the strategic direction and overall quality and coherence of the SEBoK.

SEBoK Managing Editor

Chris Hoffman

INCOSE, Cummins Inc.

christopher.hoffman@incose.net [3]

Responsible for the the day-to-day operations of the SEBoK and supports the Editor in Chief.

You can reach out to both the Editor in Chief and the Managing Editor by emailing sebok@incose.net [4].

Each Editor has their area(s) of responsibility, or shared responsibility, highlighted in the table below.

SEBoK Part 1: SEBoK Introduction

Lead Editor: Nicole Hutchison

Virginia Tech National Security Institute

emtnicole@gmail.com [2]

SEBoK Part 2: Foundations of Systems Engineering

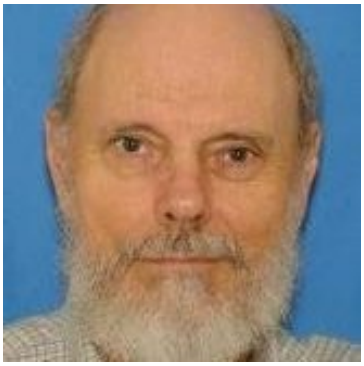
Lead Editor: Gary Smith (UK) *Airbus and International Society for the System Sciences*
grs0036@gmail.com [5]

Responsible for the System Science Foundations of System Engineering.

Assistant Editor: Dov Dori

Massachusetts Institute of Technology (USA) and Technion Israel Institute of Technology (Israel)
dori@mit.edu [6]

Responsible for the Representing Systems with Models knowledge area



Assistant Editor: Duane Hybertson

MITRE (USA)
dhyberts@mitre.org [7]

Jointly responsible for the Systems Fundamentals, Systems Science and Systems Thinking knowledge areas.

Assistant Editor: Peter Tuddenham

College of Exploration (USA)
Peter@coexploration.net [8]

Assistant Editor: Cihan Dagli

Missouri University of Science & Technology (USA)
dagli@mst.edu [9]

Responsible for the Systems Approach Applied to Engineered Systems knowledge areas.

SEBoK Part 3: Systems Engineering and Management

Lead Editor: David Endler

Lead Editor of ISO/IEC/IEEE 15288 and ISO/IEC/IEEE 24748-2, Systems Engineering Consultant – Freelancer

de@davidendler.de [10]

Assistant Editor: Cecelia Haskins

INCOSE

cecilia.haskins@incose.net [11]

SEBoK Part 4: Applications of Systems Engineering

Lead Editor: Tom McDermott

Systems Engineering Research Center (SERC)

tmcdermo@stevens.edu [12]

Assistant Editor: Javier Calvo-Amodio

Oregon State University

Javier.Calvo@oregonstate.edu [13]

Assistant Editor: Judith Dahmann

MITRE Corporation (USA)

jdahmann@mitre.org [14]

Jointly responsible for Product Systems Engineering and Systems of Systems (SoS) knowledge areas.

Assistant Editor: Michael Henshaw

Loughborough University (UK)

M.J.d.Henshaw@lboro.ac.uk [15]

Jointly responsible for Product Systems Engineering and Systems of Systems (SoS) knowledge areas

SEBoK Part 5: Enabling Systems Engineering

Lead Editor: Nicole Hutchison

Virginia Tech National Security Institute

emtnicole@gmail.com [2]

Assistant Editor: Emma Sparks

Cranfield University

Assistant Editor: Rick Hefner

California Institute of Technology

rhefner@caltech.edu [16]

Jointly responsible for the Enabling Individuals and Enabling Teams knowledge areas.

SEBoK Part 6: Related Disciplines

Lead Editor: Caitlyn Singam

University of Maryland, College Park

Caitlyn.Singam@incose.net [17] or csingam@umd.edu [18]

SEBoK Part 7: Systems Engineering Implementation Examples

Lead Editor: Chris Hoffman

INCOSE, Cummins Inc.

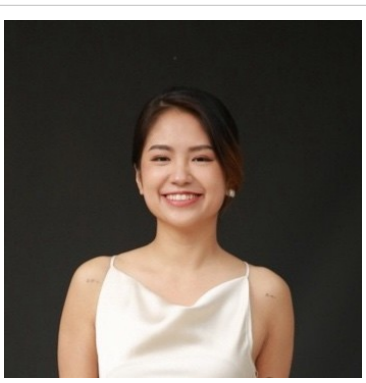
christopher.hoffman@incose.net [3]

SEBoK Part 8: Emerging Knowledge

Lead Editor: Ali Raz

George Mason University

araz@gmu.edu [19]



Assistant Editor: Ha Phuong Le

Purdue University

haple104@gmail.com [20]

SEBoK Cross-Cutting: Digital Engineering

Lead Editor: Ray Madachy

Naval Postgraduate School

rjmadach@nps.edu [21]

SEBoK Cross-Cutting: Standards

Lead Editor: David Endler

Lead Editor of ISO/IEC/IEEE 15288 and ISO/IEC/IEEE 24748-2, Systems Engineering Consultant – Freelancer

de@davidendler.de [10]

The Cross-Cutting Standards team consists of the following reviewers, who provide valuable recommendations to the SEBoK Editorial Board for updates and improvements:

- **Bill Bearden**
- **Dr. Judith Dahmann**
- **Alan Harding**
- **Garry Roedler**
- **Dr. Mike Yokell**

Student Editor

The SEBoK Student Editor plays a key role in supporting the maintenance, visibility, and growth of the Systems Engineering Body of Knowledge (SEBoK). This position includes both traditional editorial tasks and high-impact contributions to outreach and analytics. It is ideal for students interested in systems engineering, digital publishing, data visualization, and science/engineering communication.

Interested in Editing?

The Editor in Chief is looking for additional assistant editors to support the evolution of the SEBoK. Assistant editors are responsible for maintaining and updating one to two knowledge areas, including recruiting and working with authors, ensuring the incorporation of community feedback, and maintaining the quality of SEBoK content.

View the current openings at Get Involved.

If you are interested in being considered for participation on the Editorial Board, please contact the SEBoK Staff directly at sebok@incose.net [4].

Acknowledgements and Release History

This article describes the contributors to the current version of the SEBoK. For information on contributors to past versions of the SEBoK, please follow the links under "SEBoK Release History" below.

The BKCASE Project began in the fall of 2009. Its aim was to add to the professional practice of systems engineering by creating two closely related products:

- *Guide to the Systems Engineering Body of Knowledge (SEBoK)*
- *Graduate Reference Curriculum for Systems Engineering (GRCSE)*

BKCASE History, Motivation, and Value

The **Guide to the Systems Engineering Body of Knowledge (SEBoK)** is a living authoritative guide that discusses knowledge relevant to Systems Engineering. It defines how that knowledge should be structured to facilitate understanding, and what reference sources are the most important to the discipline. The curriculum guidance in the **Graduate Reference Curriculum for Systems Engineering (GRCSE)** (Pyster and Olwell et al. 2015) makes reference to sections of the SEBoK to define its core knowledge; it also suggests broader program outcomes and objectives which reflect aspects of the professional practice of systems engineering as discussed across the SEBoK.

Between 2009 and 2012, BKCASE was led by Stevens Institute of Technology and the Naval Postgraduate School in coordination with several professional societies and sponsored by the U.S. Department of Defense (DoD), which provided generous funding. More than 75 authors and many other reviewers and supporters from dozens of companies, universities, and professional societies across 10 countries contributed many thousands of hours writing the SEBoK articles; their organizations provided significant other contributions in-kind.

The SEBoK came into being through recognition that the systems engineering discipline could benefit greatly by having a living authoritative guide closely related to those groups developing guidance on advancing the practice, education, research, work force development, professional certification, standards, etc.

At the beginning of 2013, BKCASE transitioned to a new governance model with shared stewardship between the Systems Engineering Research Center (SERC) [1], the International Council on Systems Engineering (INCOSE) [2], and the Institute of Electrical and Electronics Engineers Computer Society (IEEE-CS) [3]. This governance structure was formalized in a memorandum of understanding between the three stewards that was finalized in spring of 2013 and subsequently updated. In January 2020, the IEEE Systems Council [4] replaced the IEEE-CS in representing IEEE as a steward. The stewards have reconfirmed their commitment to making the SEBoK available at no cost to all users, a key principle of BKCASE.

At of the end of 2024, SEBoK articles have had over 8.6M pageviews from more than 3.5M unique visitors. We hope the SEBoK will regularly be used by thousands of systems engineers and others around the world as they undertake technical activities such as eliciting requirements, creating systems architectures, or analyzing system test results; and professional development activities such as developing career paths for systems engineers, and deciding new curricula for systems engineering university programs.

Governance

The SEBoK is shaped by the SEBoK Editorial Board and is overseen by the BKCASE Governing Board. A complete list of members for each of these bodies can be found on the BKCASE Governance and Editorial Board page.

Content and Feature Updates for version 2.13

This version was released on 17 November 2025. The Editorial Board continues to incorporate updates to reflect v. 5 of the INCOSE *Handbook* and the 2023 version of ISO/IEC/IEEE 15288. In some instances, substantive rework was completed to reflect the current versions and changes will continue into the next releases of the SEBoK.

New articles are highlighted in the left-hand outline, in the SEBoK Table of Contents, and are elaborated below.

We welcome you to Get Involved with SEBoK via the content review form. Thank you for your engagement!

Part 2

- The Nature of Systems Knowledge Area is significantly expanded with eight new articles complementing the existing two renamed articles.
  - New and renamed articles are: Engineered Systems (was "Types of Systems"), Natural Systems, Principles and Attributes of Natural Systems, Value Proposition for Systems Engineering, Identity and Togetherness of Systems, Behavior and Dynamics of Systems, Cycles and the Phases of Systems (was "Cycles and the Cyclic Nature of Systems"), Purpose and the Capability of Systems, Value and the Quality of Systems, and Consciousness and the Experience of Systems.

Part 3

- A new sub-part on **Process Concepts** has been added in two Knowledge Areas and 5 articles.
  - Process Concepts Knowledge Area with new articles Process Description and Process Concurrency, Iteration, and Recursion.
  - Process Selection and Tailoring Knowledge Area with new articles Guidelines for the Selection and Tailoring of Processes, Using ISO/IEC/IEEE 24748-2, and Tailoring.
- Updates have been made to the following articles in the Technical Management Processes Knowledge Area (renamed from "Systems Engineering Management").
  - Project Planning (was "Technical Planning"), Project Assessment and Control (was "Assessment and Control"), Decision Management, Risk Management, Configuration Management, Information Management, and Measurement.

SEBoK Release History

There have been 25 releases of the SEBoK to date.

Main Releases

- Version 2.13 - Current release.
- Version 2.12 - This release included many changes to reflect v. 5 of the INCOSE *Handbook* and the 2023 version of [ISO/IEC/IEEE 15288]. In some instances, substantive rework was completed to reflect the current versions and changes will continue into the next releases of the SEBoK.
- Version 2.11 - Three new articles were added in this release, Barriers to Successful Embedding of Systems Engineering into Organizations, Cost Estimating and Analysis in Systems Engineering, and Resilience Modeling with an updated introduction to the Related Disciplines article.
- Version 2.10 - This release formally invited readers to Get Involved through a new content review form, renamed and reorganized several articles in Part 3 to reflect current practice, and published a new System Architecture Design Definition article.
- Version 2.9 - The first release with Editor-in-Chief Nicole Hutchison and Managing Editor Chris Hoffman. New articles included Reverse Engineering a UAV Prototype using Agile Practices, System Security, and An overview of the SWEBOK Guide. Updated articles on Loss Driven Systems Engineering, System Resilience, and a change to persona-driven SEBoK user guidance instead of use cases that were introduced in v. 1.0.
- Version 2.8 - This release included new articles on systems engineering and enterprise IT, and system adaptability; minor updates to several articles throughout the wiki; imrpovements to the wiki infrastructure; and Rob Cloutier's final edition of the SEBoK as Editor-in-Chief.
- Version 2.7 - This release included new articles on loss-driven systems engineering and the history of systems engineering; updates to the article on systems and industrial engineering; and minor updates to improve resources and align with evolving practices throughout part 3, including in the articles around systems engineering standards and to the articles in Part 5, particularly the addition of new resources. There were also some improvements in the SEBoK wiki infrastructure.
- Version 2.6 - This update included substantial evolution of Parts 2 and 3, the foundations of systems engineering and systems engineering approaches, methods, processes, and tools. The version also included more information on Model-Based Systems Engineering (MBSE) and Digital Engineering, refinement of systems science foundations of systems engineering, and a new article on agile approaches. In Part 6 there were many new articles and updates to existing articles on the relationships between systems engineering and other disciplines.
- Version 2.5 - This version included an update of the main page; creation of the Editor's Corner; new sponsors and sponsorship packages; new navigation in the left-hand menu; small edits to address the comments received from the community. This release also updated to the latest version of MediaWiki, tightened up the IT infrastructure, and made some adjustments to improve performance.
- Version 2.4 - This was a minor release, including reorganizations of Part 6 and 8 to handle new knowledge areas and topics. In addition, several new articles were added, including, Systems Engineering Heuristics, Diversity, Equity, and Inclusion, Systems Engineering and Geospatial/Geodetic Engineering Knowledge Area, System Hardware Assurance, Socio-technical Systems, Verification and Validation of Systems in Which AI is a Key Element, and an introductory article on Artificial Intelligence. The content on Systems of Systems (SoS) was also updated.
- Version 2.3 - This was a minor release, including two new articles: Cycles and the Phases of Systems and Portfolio Management. A number of additional minor edits, including a new overview graphic for the SEBoK, cleanup of existing pages, software updates, etc. were incorporated.
- Version 2.2 - This was a significant release, including the first new Part to be added since v. 1.0 - Emerging Knowledge - which is a place to highlight new topics in systems engineering that are important but may not yet

have a large body of literature. Recent dissertations around emerging topics are also included. A new case study on Apollo 1 was added to Part 7, which has also been reorganized around topics. Additional minor updates have occurred throughout.

- Version 2.1 - This was a significant release with new articles, new functionality, and minor updates throughout.
- Version 2.0 - This was a major release of the SEBoK which included incorporation of multi-media and a number of changes to the functions of the SEBoK.
- Version 1.9.1 - This was a micro release of the SEBoK which included updates to the editorial board, and a number of updates to the wiki software.
- Version 1.9 - This was a minor update which included updates to the System Resilience article in Part 6: Related Disciplines, as well as a major restructuring of Part 7: Systems Engineering Implementation Examples. A new example has been added around the use of model based systems engineering for the thirty-meter telescope.
- Version 1.8 - This was a minor update, including an update of the Systems of Systems (SoS) knowledge area in Part 4: Applications of Systems Engineering where a number of articles were updated on the basis of developments in the area as well as on comments from the SoS and SE community. Part 6: Related Disciplines included updates to the Manufacturability and Producibility and Reliability, Availability, and Maintainability articles.
- Version 1.7 - This was a minor update, including a new Healthcare SE Knowledge Area (KA), expansion of the MBSE area with two new articles, Technical Leadership and Reliability, Availability, and Maintainability and a new case study on the Northwest Hydro System.
- Version 1.6 - This was a minor update, including a reorganization of Part 1 SEBoK Introduction, a new article on the Transition towards Model Based Systems Engineering and a new article giving an overview of Healthcare Systems Engineering, a restructure of the "Systems Engineering and Specialty Engineering" (now Systems Engineering and Quality Attributes) KA.
- Version 1.5 - This was a minor update, including a restructure and extension of the Software Engineering Knowledge Area, two new case studies, and a number of corrections of typographical errors and updates of outdated references throughout the SEBoK.
- Version 1.4 - This was a minor update, including changes related to ISO/IEC/IEEE 15288:2015 standard, three new case studies and updates to a number of articles.
- Version 1.3 - This was a minor update, including three new case studies, a new use case, updates to several existing articles, and updates to references.
- Version 1.2 - This was a minor update, including two new articles and a revision of several existing articles.
- Version 1.1 - This was a minor update that made modest content improvements.
- Version 1.0 - This was the first official version of the SEBoK intended for broad use and was released 15 September 2012.

Click on the links above to read more information about each release.

Get Involved

The SEBoK is a living resource — and *you* can help shape its future!

The SEBoK is built by the community, for the community. Every article, concept, and framework in the SEBoK exists because professionals like you contributed their time, insight, and expertise to improve our shared understanding of systems engineering.

Whether you're a seasoned practitioner, a researcher, an educator, or a student, there's a place for you in this global effort.

Why Get Involved?

There are a variety of reasons to get engaged with the SEBoK:

- **Make an Impact:** Influence how systems engineering is understood, practiced, and taught around the world.
- **Grow Your Network:** Collaborate with thought leaders, peers, and contributors from diverse domains.
- **Expand Your Expertise:** Deepen your knowledge of key SE topics while contributing to a trusted and evolving resource.
- **Pay It Forward:** Help the next generation of systems engineers by shaping the foundational knowledge they'll rely on.

Provide Feedback

Even if you're not ready to write or edit, your feedback is valuable. Tell us what works, what doesn't, and what's missing.

Eligibility

Anyone is welcome to review the SEBoK articles, knowledge areas, glossary, and other pages. Over the life of the SEBoK, we have had several hundred reviewers, and they provide critical value by helping us ensure that our articles are accessible to the community.

To review an article of SEBoK, please use our Google Form [1] or for more general notes, email us at sebok@incose.net [4].

Become a Content Contributor

Write or revise content in your area of expertise. Whether it's a new section, an update to existing material, or integration of new methods (like model-based or digital engineering), we welcome your contributions.

Eligibility

Authors create content specifically for the SEBoK. They work with the Editorial Board to define the right scope for a topic and develop the content in compliance with our style guide. Authors are subject matter experts who can speak authoritatively and without bias and may propose new articles or edits to existing articles. Time commitment is flexible, ranging from one-time contributions to ongoing engagement.

If you are interested in becoming a SEBoK author, please contact us at sebok@incose.net [4].

Join the Editorial Board

Editorial board members guide the content, review contributions, and shape SEBoK strategy. We are always looking for individuals passionate about systems engineering and committed to the growth of the field. There are two main roles:

- **Assistant Editors** have responsibility for specific knowledge areas (collections of topics) within the SEBoK. They are subject matter experts who help to ensure that the content of their particular knowledge area is up to date and meets the quality standards of the SEBoK. Assistant editors work with our authors to improve upon or create articles.
- **Lead Editors** have responsibility for a specific part of the SEBoK (shown in Structure of the SEBoK). They help create the strategic vision for their part and coordinate the efforts of the Assistant Editors within their parts. They are responsible for the overall quality of their part and work directly with authors as appropriate.

Eligibility

To become a SEBoK editor, you need to have proven expertise in an area of the SEBoK. Prior experience with the SEBoK is a plus but not required.

Ready to Make a Difference?

Join us in advancing the SEBoK - reach out to sebok@incose.net [4] to start the conversation!

SEBoK Releases

The SEBoK is updated twice a year, typically the third weeks of May and November. After each release the Editorial Board and Authors begin working on the next version. This means we are always looking for inputs - it's always a good time to engage!

Below are the deadlines for the upcoming Spring 2026 release. Deliverables are strongly encouraged to be completed sooner than the deadlines.

- **12 weeks to publication (23 February 2026):** Lead Editors have finalized proposed changes to SEBoK articles (titles and intent only, not content).
- **9 weeks to publication (16 March 2026):** Authors have submitted Intellectual Property releases for new authors and new figures.
- **6 weeks to publication (6 April 2026):** Editors have submitted SEBoK Architecture (Table of Contents) changes (adds, removes, renames, moves).
- **2 weeks to publication (4 May 2026):** Authors and Editors have finalized and uploaded all content into the draft SEBoK.

- **1 week to publication (11 May 2026):** Lead Editors have reviewed, made final edits, and approved the uploaded content.
- **Weekend prior & day of publication (18 May 2026):** Managing Editor and Editor-in-Chief final review, creation of PDF, content is published.

Open Positions

The SEBoK Editorial Board is currently looking for Assistant Editors to support Part 3: Systems Engineering and Management (particularly MBSE/digital engineering practitioners), Part 4: Applications of Systems Engineering, and Part 6: Related Disciplines. We are also looking for a Lead Editor for Part 5: Enabling Systems Engineering and Part 7: Systems Engineering Implementation Examples. If you have an interest in any of these roles, please contact us at sebok@incose.net [4].

Contact Us

If you have any questions about how to engage with the SEBoK, please reach out to the Editorial Board at sebok@incose.net [4]. We look forward to hearing from you!

  1. What is a Model?
  2. Why Model?
  3. Types of Models
  4. System Modeling Concepts
  5. Integrating Supporting Aspects into System Models
  6. Modeling Standards
- Knowledge Area: Systems Approach Applied to Engineered Systems
  1. Overview of the Systems Approach
  2. Engineered System Context
  3. Identifying and Understanding Problems and Opportunities
  4. Synthesizing Possible Solutions
  5. Analysis and Selection between Alternative Solutions
  6. Implementing and Proving a Solution
  7. Deploying, Using, and Sustaining Systems to Solve Problems
  8. Applying the Systems Approach

Part 3: Systems Engineering and Management

- Systems Engineering STEM Overview
- Model-Based Systems Engineering (MBSE)

Part 3A - Life Cycle Concepts

- Knowledge Area: Life Cycle Terms and Concepts
  1. Life Cycle Concepts
  2. Life Cycle Models
  3. Life Cycle Stages
  4. Technical Reviews and Audits
- Knowledge Area: Development Approaches
  1. Development Approach Concepts
  2. Sequential Development Approach

3. Incremental Development Approach
4. Evolutionary Development Approach
5. Agile Development Approach
6. Lean Engineering

- Knowledge Area - Agile Systems Engineering
  1. Agile Systems Engineering
  2. Industrial DevOps
- Knowledge Area - Life Cycle Model Selection and Adaptation
  1. Selecting the Life Cycle Model
  2. Adapting the Life Cycle Model
  3. Selecting the Development Approach
  4. Adapting the Development Approach
  5. Applying Life Cycle Processes

Part 3B - Process Concepts

- Knowledge Area: Process Concepts - New Knowledge Area
  1. Process Description - New Article
  2. Process Concurrency, Iteration, and Recursion - New Article
- Knowledge Area – Process Selection and Tailoring - New Knowledge Area
  1. Guidelines for the Selection and Tailoring of Processes - New Article
  2. Using ISO/IEC/IEEE 24748-2 - New Article
  3. Tailoring - New Article

Part 3C: Processes

- Knowledge Area: Technical Management Processes - Renamed Knowledge Area (was "Systems Engineering Management")
  1. Project Planning - Renamed Article (was "Technical Planning)
  2. Project Assessment and Control - Renamed Article (was "Assessment and Control")
  3. Decision Management
  4. Requirements Management
  5. Risk Management
  6. Configuration Management
  7. Configuration Baselines
  8. Configuration Management Implementation
  9. Information Management
  10. Quality Management
  11. Measurement
- Knowledge Area: System Concept Definition
  1. Business or Mission Analysis
  2. Stakeholder Needs Definition
- System Requirements Definition
- Knowledge Area: System Architecture Design Definition
  1. Functional Architecture
  2. Logical Architecture
  3. Physical Architecture
- System Detailed Design Definition
- System Analysis

- System Realization
- System Implementation
- System Integration
- System Verification
- System Transition
- System Validation
- System Operation
- Knowledge Area: System Maintenance
  1. Logistics
  2. Service Life Management
  3. Service Life Extension
  4. Capability Updates, Upgrades, and Modernization
  5. System Disposal and Retirement

Part 3D - Relevant Standards

- Knowledge Area: Systems Engineering Standards
  1. Why Standards?
  2. Systems Engineering Related Standards Landscape
  3. Alignment and Comparison of Systems Engineering Standards
  4. Application of Systems Engineering Standards

Part 4: Applications of Systems Engineering

- Knowledge Area: Product Systems Engineering
  1. Product Systems Engineering Background
  2. Product as a System Fundamentals
  3. Business Activities Related to Product Systems Engineering
  4. Product Systems Engineering Key Aspects
  5. Product Systems Engineering Special Activities
- Knowledge Area: Service Systems Engineering
  1. Service Systems Background
  2. Fundamentals of Services
  3. Properties of Services
  4. Scope of Service Systems Engineering
  5. Value of Service Systems Engineering
  6. Service Systems Engineering Stages
- Knowledge Area: Enterprise Systems Engineering
  1. Enterprise Systems Engineering Background
  2. The Enterprise as a System
  3. Related Business Activities
  4. Enterprise Systems Engineering Key Concepts
  5. Enterprise Systems Engineering Process Activities
  6. Enterprise Capability Management
- Knowledge Area: Systems of Systems (SoS)
  1. Architecting Approaches for Systems of Systems
  2. Systems Engineering for Systems of Systems
  3. Systems of Systems Analytic Approaches

4. System of Systems and Complexity
5. Socio-Technical Features of Systems of Systems
6. Capability Engineering
7. Mission Engineering

- Knowledge Area: Healthcare Systems Engineering
  1. Overview of the Healthcare Sector
  2. Systems Engineering in Healthcare Delivery
  3. Systems Biology
  4. Lean in Healthcare

Part 5: Enabling Systems Engineering

- Knowledge Area: Enabling Businesses and Enterprises
  1. Systems Engineering Organizational Strategy
  2. Determining Needed Systems Engineering Capabilities in Businesses and Enterprises
  3. Organizing Business and Enterprises to Perform Systems Engineering
  4. Assessing Systems Engineering Performance of Business and Enterprises
  5. Developing Systems Engineering Capabilities within Businesses and Enterprises
  6. Barriers to Successful Embedding of Systems Engineering into Organizations
  7. Culture
- Knowledge Area: Enabling Teams
  1. Team Capability
  2. Team Dynamics
  3. Diversity, Equity, and Inclusion
  4. Technical Leadership in Systems Engineering
- Knowledge Area: Enabling Individuals
  1. Roles and Competencies
  2. Assessing Individuals
  3. Developing Individuals
  4. Ethical Behavior

Part 6: Related Disciplines

- Knowledge Area: Systems Engineering and Environmental Engineering
- Knowledge Area: Systems Engineering and Geospatial/Geodetic Engineering
  1. Overview of Geospatial/Geodetic Engineering
  2. Relationship between Systems Engineering and Geospatial/Geodetic Engineering
  3. Further Insights into Geospatial/Geodetic Engineering
- Knowledge Area: Systems Engineering and Industrial Engineering
- Knowledge Area: Systems Engineering and Project Management
  1. The Nature of Project Management
  2. An Overview of the PMBOK® Guide
  3. Relationships between Systems Engineering and Project Management
  4. The Influence of Project Structure and Governance on Systems Engineering and Project Management Relationships
  5. Cost Estimating and Analysis in Systems Engineering
  6. Procurement and Acquisition

7. Portfolio Management
- Knowledge Area: Systems Engineering and Software Engineering
  1. Software Engineering in the Systems Engineering Life Cycle
  2. The Nature of Software
  3. An Overview of the SWEBOK Guide
  4. Key Points a Systems Engineer Needs to Know about Software Engineering
  5. Software Engineering Features - Models, Methods, Tools, Standards, and Metrics

Part 1: SEBoK Introduction

SEBoK Introduction

Contents of this Part

- Introduction to the SEBoK
- Introduction to Systems Engineering
- SEBoK Users and Uses

-

The purpose of the *Guide to the Systems Engineering Body of Knowledge (SEBoK)* is to provide a widely accepted, community-based, and regularly updated baseline of systems engineering (SE) knowledge. SEBoK Part 1 contains an introduction to both the discipline of SE, and an introduction to and guide for the use of the SEBoK wiki.

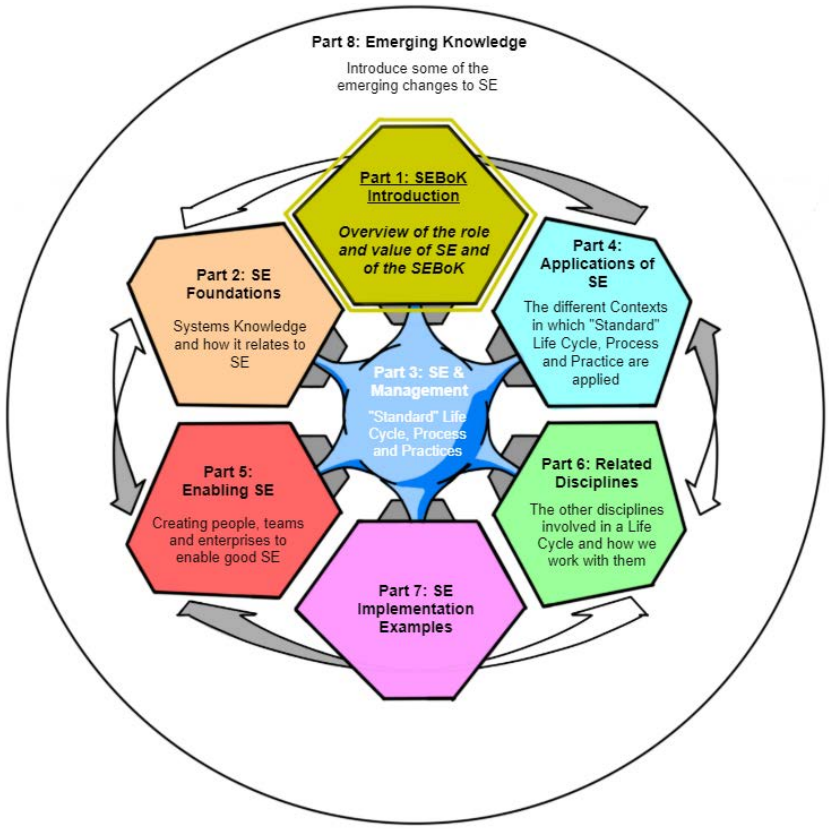

Figure 1. SEBoK Part 1 in context (SEBoK Original). For more detail see Structure of the SEBoK

Part 1 also includes an introduction to some of the emerging aspects of systems engineering and a discussion of how these are transforming the discipline. As this knowledge matures, it will be migrated into the main body of the SEBoK.

Part 1 Knowledge Areas

Each part of the SEBoK is divided into knowledge areas (KAs), which are groupings of information with a related theme. Part 1 contains the following KAs:

- Introduction to the SEBoK
- Introduction to Systems Engineering
- Introduction to SE Transformation
- SEBoK Users and Uses

Scope and Context of the SEBoK

While Part 1 introduces Systems Engineering knowledge areas, the remaining SEBoK content (Parts 2 – 6) focuses on domain-independent information—that which is universal to systems engineering regardless of the domain in which it is applied. Part 7 includes examples from real projects. These illustrate the concepts discussed elsewhere in the SEBoK, while detailing considerations relevant to domains such as aerospace, medicine, and transportation. Part 8 is intended to introduce some of the more significant emerging changes to systems engineering, both in general topics and emerging research.

SE in the context of engineered systems (ES) is the primary scope for the SEBoK, though general systems concepts are also discussed in Part 2. The SEBoK also covers considerations for the disciplines of software engineering and project management, which are strongly intertwined with the practice of SE (see Part 6).

Introduction to the SEBoK

Introduction to the SEBoK

Contents of this Knowledge Area

- Scope of the SEBoK
- Structure of the SEBoK

-

The SEBoK provides a widely accepted, community-based, and regularly updated baseline of systems engineering (SE) knowledge. Therefore, it is a curated body of knowledge which is updated on a semi-annual basis. This baseline strengthens the mutual understanding across the many disciplines involved in developing and operating systems.

Topics

Each part of the SEBoK is divided into KAs (knowledge areas), which are groupings of information with a related theme. The KAs are divided into topics. This KA contains the following topics:

- Scope of the SEBoK
- Structure of the SEBoK

Scope of the SEBoK

-

The SEBoK is a large, curated compendium of information about systems engineering. It:

- is a guide to the body of SE knowledge which provides references to detailed sources for additional information; it is not a self-contained knowledge resource
- focuses on Engineered Systems contexts, that is socio-technical systems with a recognized SE life cycle, while treating social and natural systems as relevant and important environmental considerations (see Part 2)
- describes generic SE life cycle and process knowledge (see Part 3)
- recognizes that SE principles can be applied differently to different types of products, services, enterprises, and systems of systems (SoS) context (see Part 4)
- provides resources for organization support of SE activities (see Part 5)
- explores the interaction between SE and other disciplines, highlighting what systems engineers need to know about these disciplines (see Part 6)
- is domain-independent, with implementation examples to provide domain-specific context (see Part 7)

Each of these considerations depends upon the definition and scope of SE itself, which is the subject of the next section.

SEBoK Purposes

Ongoing studies of system cost and schedule failures (Gruhl & Stutzke 2005; Johnson 2006, GAO 2016) and safety failures (Leveson 2012) have shown that the failures have mostly come not from their domain disciplines, but from lack of adequate Systems Engineering (NDIA 2003, 2006, 2016). To provide a foundation for the mutual understanding of SE needed to reduce these failures, the SEBoK describes the boundaries, terminology, content, and structure of SE. In so doing, the SEBoK systematically and consistently supports six broad purposes, described in Table 1.

Table 1. SEBoK Purposes. (SEBoK Original)

#	Purpose	Description
1	Inform Practice	Inform systems engineers about the boundaries, terminology, and structure of their discipline and point them to useful information needed to practice SE in any application domain.
2	Inform Research	Inform researchers about the limitations and gaps in current SE knowledge that should help guide their research agenda.
3	Inform Interactors	Inform performers in interacting disciplines (system implementation, project and enterprise management, other disciplines) and other stakeholders of the nature and value of SE.
4	Inform Curriculum Developers	Inform organizations defining the content that should be common in undergraduate and graduate programs in SE.
5	Inform Certifiers	Inform organizations certifying individuals as qualified to practice systems engineering.
6	Inform SE Staffing	Inform organizations and managers deciding which competencies practicing systems engineers should possess in various roles ranging from apprentice to expert.

The SEBoK is a guide to the body of SE knowledge, not an attempt to capture that knowledge directly. It provides references to more detailed sources of knowledge, all of which are generally available to any interested reader. No proprietary information is referenced, but not all referenced material is free—for example, some books or standards must be purchased from their publishers. The criterion for including a source is simply that the authors & editors believed it offered the best generally available information on a particular subject.

The SEBoK is global in applicability. Although SE is practiced differently from industry to industry and country to country, the SEBoK is written to be useful to systems engineers anywhere. The authors & editors were chosen from diverse locales and industries, and have refined the SEBoK to broaden applicability based on extensive global reviews of several drafts.

The SEBoK aims to inform a wide variety of user communities about essential SE concepts and practices in ways that can be tailored to different enterprises and activities while retaining greater commonality and consistency than would be possible without the SEBoK. Because the world in which SE is being applied continues to evolve and is dynamic, the SEBoK is designed for easy, continuous updating as new sources of knowledge emerge.

SEBoK Uses

The communities involved with SE include its various specialists, engineers from disciplines other than systems engineering, managers, researchers, and educators. This diversity means that there is no single best way to use the SEBoK. The SEBoK includes use cases that highlight potential ways that particular communities can draw upon the content of the SEBoK, identify articles of interest to those communities, and discuss primary users (those who use the SEBoK directly) and secondary users (those who use the SEBoK with assistance from a systems engineer). For more on this, see the article SEBoK Users and Uses.

SEBoK Domain Independent Context

The SEBoK uses language and concepts that are generally accepted for domain-independent SE. For example, the domain-independent conceptual foundations of SE are elaborated in Part 2: Foundations of Systems Engineering. However, each of the numerous domains in which SE is practiced — including telecommunications, finance, medicine, and aerospace — has its own specialized vocabulary and key concepts. Accordingly, the SEBoK is designed to show how its domain-independent material relates to individual domains in two ways.

Firstly, by means of examples that tell stories of how SE is applied in particular domains. Part 7: Systems Engineering Implementation Examples) consists of examples (case studies and vignettes), each set in a particular domain such as aerospace, medicine, or software, and featuring vocabulary and concepts special to that domain. There are similar vignettes in some of the Use Cases in Part 1. These examples demonstrate the effect of domain on the application of SE and complement the domain-independent information elsewhere in the SEBoK. They show how a concept works in a given domain and provide a fair opportunity for reviewers to reflect on whether there are better ways to capture application-dependent aspects of SE knowledge.

In addition, the SEBoK will contain knowledge areas in Part 4: Applications of Systems Engineering which explicitly describe the domain specific language, approaches, specialized processes and tools, etc. of particular application domains. In this version of the SEBoK, there are a limited set of domain knowledge areas.

Structure of the SEBoK

-

The **Guide to the Systems Engineering Body of Knowledge (SEBoK)** is a living authoritative guide that discusses knowledge relevant to Systems Engineering. SEBoK does not contain all of this knowledge itself but provides a starting point and key resources to allow the reader to navigate the wider body of knowledge that exists in published sources. To do this, SEBoK:

- Defines relevant knowledge and structures it to facilitate understanding.
- Provides short discussions of key ideas, principles and concepts within that structure.
- Points to reference sources important to the discipline, which explore these ideas in more detail.

In doing this, it is inevitable that differences in terminology, alternative approaches, and even fundamentally different ways of thinking within the knowledge will appear. SEBoK attempts were possible to provide clarity of similar or overlapping ideas, or to highlight real differences and the reasons behind them. In particular, the SEBoK Glossary of Terms contains the most used or generally agreed upon definitions of terms when it can, but may highlight more than one definition if needed to show breadth of current thinking.

SEBoK Structure

Figure 1, below, illustrates the eight parts of the SEBoK and how they are related.

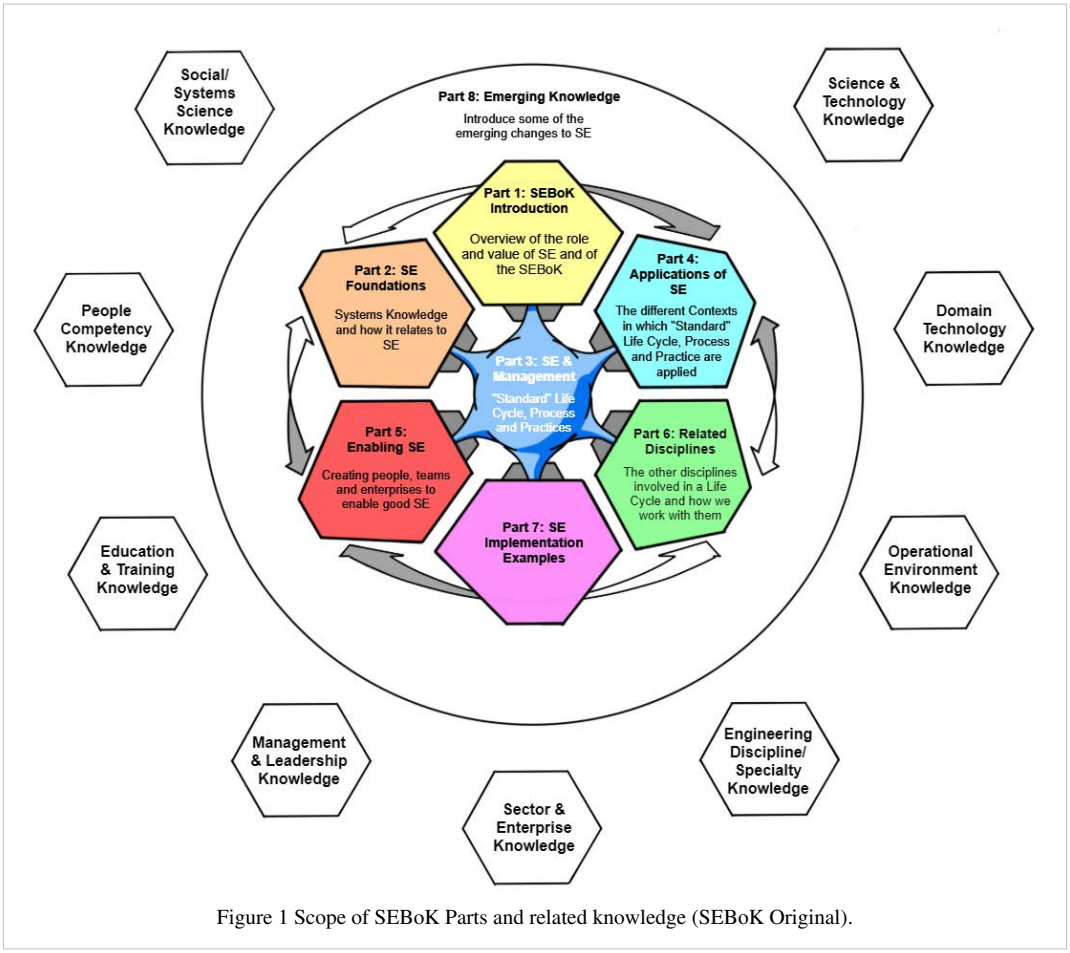

Figure 1 Scope of SEBoK Parts and related knowledge (SEBoK Original).

The scope of each part and the key relationships amongst them are briefly discussed below. For a more detailed discussion of how this structure was evolved, see (Adcock et al, 2016).

Overview of Parts

Part 1: SEBoK Introduction

This part explains the scope, context, and structure of the SEBoK, and of systems engineering (SE).

An overview of who should use the SEBoK, and for what purpose, is followed by detailed use cases. Systems engineering's economic value, history, and relationship to other disciplines are discussed. Part 1 also contains a section which discusses the future evolution of the SEBoK and allows for new areas of content to be introduced before being transitioned into other SEBoK parts.

Part 2: Foundations of Systems Engineering

This part provides an introduction and overview of areas of knowledge which provide the foundations of SE.

A discussion of the definitions and basic concepts of systems is followed by an overview of the principles, concepts, methods, models and patterns of some of the key foundational areas of systems science. This includes a detailed consideration of the foundational knowledge related to systems models and modelling.

Part 2 looks in more detail at two aspects of this foundational knowledge of particular value to SE. The first is to discuss aspects of systems knowledge related to a systems approach to complex problems and opportunities. This approach provides foundations for how SE is defined and practiced (see Parts 3 and 5 below). The second is to describe the different ways in which system concepts are applied to real world concerns. The SEBoK defines an engineered system (ES) as the primary focus for the application of SE (see Part 4 below).

Part 3: Systems Engineering and Management

This part describes generic knowledge on the practice of SE and related management activities.

Part 3 begins with the life cycle models common in SE and the general principles behind their application. It then moves on to SE management activities. It covers both technical activities such as requirements, architecture, test and evaluation; and management activities such as planning, measurement, and risk. Next is product and service life management, a distinct area of SE management that emphasizes the entire life cycle including retirement and disposal. An account of SE standards concludes this part.

Focused on what many think of as the main body of SE, including best practices and common pitfalls, this part constitutes a substantial proportion of the SEBoK. As already discussed, the knowledge in Part 3 is based on the systems approach from Part 2. The links between Part 3 and the other parts of the SEBoK are discussed below.

Part 4: Applications of Systems Engineering

This part describes how to apply SE principles to different types of system context.

Part 4 focuses on four major engineered system contexts in turn: products, services, enterprises, and systems of systems (SoS). For each one, the system abstraction, commercial relationships and application of generic SE is described.

The generalized contexts above should be viewed as overlapping models of how SE can be applied in different kinds of situations. Combinations of one or more of them are fully realized when applied in an application domain. Part 4 currently describes this application in a small number of such domains. This will be expanded in later updates. The applications of SE in this part describe the real-world practice of SE. The generalized knowledge in both Parts 2 and 3 evolves through what we learn from these applications. Part 2 includes a discussion of this relationship between theory and practice.

Part 5: Enabling Systems Engineering

This part describes approaches to organization that may enable the successful performance of SE activities.

Part 4 covers knowledge at the enterprise, team, or individual level. The range of considerations extends from value proposition, business purpose, and governance, down to competency, personal development as a systems engineer, and ethics.

All of these relate to the baseline definitions of SE in Part 3, further generalized in the levels of application in Part 4. The systems approach in Part 2 should also form a foundation for this part. Since the practice of SE is transdisciplinary, Part 5 also has a link to Part 6 as discussed below.

Part 6: Related Disciplines

This part describes the relationships between SE and other disciplines.

Part 6 covers the links between SE and software engineering (SwE), project management (PM), industrial engineering (IE) and procurement. It also describes how SE is related to specialty engineering, which describes the various system "–ilities" (like reliability, availability, and maintainability) that SE must balance and integrate.

The knowledge in this part provides an interface to other bodies of knowledge, focused on how it is linked to Parts 3, 4 and 5 above.

Part 7: Systems Engineering Implementation Examples

A set of real-world examples of SE activities demonstrates implementations of the systems engineering knowledge in previous parts of the SEBoK. These examples come in two forms: case studies, which refer the reader to and summarize published examinations of the successes and challenges of SE programs, and vignettes, which are brief, self-contained wiki articles. This part is a key place to look within the SEBoK for lessons learned, best practices, and patterns. Many links connect material in the examples to the conceptual, methodological, and other content elsewhere in the SEBoK.

Part 8: Emerging Knowledge

One of the challenges associated with a body of knowledge is that cutting edge and/or emerging ideas are difficult to include. Bodies of knowledge are based on existing literature and resources, and these often do not exist for new topics. To address this, Part 8 of the SEBoK contains those emerging ideas and items that are not easily covered in the other sections of the SEBoK. As these areas mature and as a body of literature is created around them, they will be moved into the other Parts of the SEBoK.

Addenda

The SEBoK contains a Glossary of Terms, which provides authoritatively-referenced definitions of key terms. This information is displayed when the reader hovers the mouse pointer over a glossary term within an article. It also contains a list of Primary References, with additional information about each reference. Quicklinks in the left margin provide additional background information, including a table of contents, a listing of articles by topic [1], and a list of Acronyms.

Introduction to Systems Engineering

Introduction to Systems Engineering

Contents of this Knowledge Area

- Systems Engineering Overview
- Fundamentals for Digital Engineering (Emiliya Suprun and Sondoss Elsawah)
- Economic Value of Systems Engineering
- A Brief History of Systems Engineering (Robert Cloutier) (Michael Pennotti)
- Systems Engineering: Historic and Future Challenges
- Systems Engineering and Other Disciplines
- Fundamentals for Future Systems Engineering (Rick Adcock) (Duane Hybertson)

-

The primary focus of the SEBoK is on the current baseline of knowledge describing the practice of domain independent systems engineering (SE). This Knowledge Area (KA) contains topic articles which provide an overview of SE practice and discuss its economic value, historic evolution and key relationships.

Topics

Each part of the SEBoK is divided into KAs, which are groupings of information with a related theme. The KAs, in turn, are divided into topics. This KA contains the following topics:

- Systems Engineering Overview
- Economic Value of Systems Engineering
- Systems Engineering: Historic and Future Challenges
- Systems Engineering and Other Disciplines

Systems Engineering

Systems Engineering is a transdisciplinary and integrative approach to enable the successful realization, use, and retirement of engineered systems, using systems principles and concepts, and scientific, technological, and management methods. (INCOSE 2023)

Successful systems must satisfy the needs of their customers, users and other stakeholders. Some key elements of systems engineering are highlighted in Figure 1 and include:

- The principles and concepts that characterize a system, where a system is an interacting combination of system elements that accomplish a defined objective(s). The system interacts with its environment, which may include other systems, users, and the natural environment. The system elements that compose the system may include hardware, software, firmware, people, information, techniques, facilities, services, and other support elements.
- A systems engineer is a person or role who supports this transdisciplinary approach. In particular, the systems engineer often serves to elicit and translate customer needs into specifications that can be realized by the system development team.
- In order to help realize successful systems, the systems engineer supports a set of life cycle processes beginning early in conceptual design and continuing throughout the life cycle of the system through its manufacture, deployment, use and disposal. The systems engineer must analyze, specify, design, and verify the system to ensure that its functional, interface, performance, physical, and other quality characteristics, and cost are balanced

to meet the needs of the system stakeholders.

- A systems engineer helps ensure the elements of the system fit together to accomplish the objectives of the whole, and ultimately satisfy the needs of the customers and other stakeholders who will acquire and use the system.

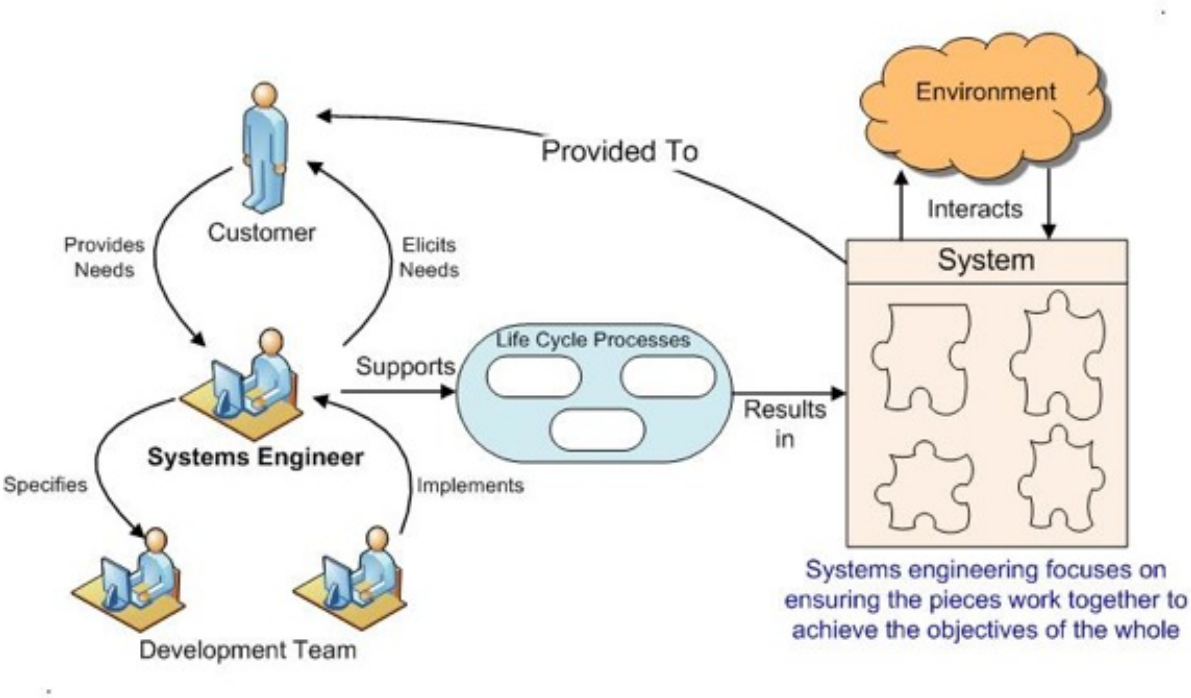

Figure 1. Key Elements of Systems Engineering. (SEBoK Original)

Systems Engineering Overview

-

Systems engineering (SE) is a transdisciplinary approach and means to enable the realization of successful systems. Successful systems must satisfy the needs of their customers, users and other stakeholders. This article discusses the complexities of systems and systems engineering (SE), highlighting how SE manages ambiguities in terminology and integrates with broader disciplines. It introduces specific SE definitions, emphasizing its focus on engineered systems and their contexts. SE's scope excludes activities like manufacturing. The article outlines SE's transdisciplinary approach and its role within the project life cycle, where it collaborates with various agents to create and evolve successful engineered systems. Notably, SE involves negotiating changes proposed by stakeholders and mediated by systems engineers. Overall, the article underscores SE's pivotal role in realizing and managing complex engineered systems within diverse environments.

Systems and Systems Engineering

In the broad community, the term “system” may mean a collection of technical, natural or social elements, or a combination of all three. This may produce ambiguities at times: for example, does “management” refer to management of the SE process, or management of the system being engineered? As with many special disciplines, SE uses terms in ways that may be unfamiliar outside the discipline. For example, in systems science and therefore SE, “open” means that a system is able to interact with its environment--as opposed to being "closed” to its environment. However, in the broader engineering world we would read “open” to mean “non-proprietary” or “publicly agreed upon.” In such cases, the SEBoK tries to avoid misinterpretation by elaborating the alternatives e.g. “system management” or “systems engineering management”.

A useful introduction to systems engineering from Colorado Technical University can be found here: https://www.youtube.com/watch?v=aZXVRvZJT4I.

The SEBoK seeks to position SE within the broader scope of knowledge which considers systems as part of its foundations. To do this without attempting to re-define general systems terminology, SEBoK introduces two related definitions specific to SE:

- An engineered system is a technical or socio-technical system which is the subject of an SE life cycle. It is a system designed or adapted to interact with an anticipated operational environment to achieve one or more intended purposes while complying with applicable constraints.
- An engineered system context centers around an engineered system but also includes in its relationships other engineered, social or natural systems in one or more defined environments.

Since the province of SE is engineered systems, most SE literature assumes this in its terminology. Thus, in an SE discussion, “system architecture” would refer to the architecture of the system being engineered (e.g., a spacecraft) and not the architecture of a natural system outside its boundary (e.g., the solar system). In fact, a spacecraft architecture would cover the wider system context including external factors such as changes in gravity and external air pressure and how these affect the spacecraft's technical and human elements. Thus, the term "system architecture" more properly refers to the engineered system context. The SEBoK tries to be more explicit about this, but may still make these kinds of assumptions when referring directly to other SE literature.

An extensive glossary of terms identifies how terms are used in the SEBoK and shows how their meanings may vary in different contexts. As needed, the glossary includes pointers to articles providing more detail.

For more about the definition of systems, see the article What is a System? in Part 2. The primary focus of SEBoK Part 3: Systems Engineering and Management and Part 4: Applications of Systems Engineering is on how to create or change an engineered system to fulfill the goals of stakeholders within these wider system contexts. The knowledge in Part 5: Enabling Systems Engineering and Part 6: Systems Engineering and Other Disciplines

examines the need for SE itself to be integrated and supported within the human activity systems in which it is performed, and the relationships between SE and other engineering and management disciplines.

Matlab created this 15-minute overview of systems engineering as a discipline: https:/ / www. youtube. com/ watch?v=pSfZutP9H-U.

Scope of Systems Engineering within the Engineered Systems Domain

The scope of SE does not include everything involved in the engineering and management of an engineered system. Activities can be part of the SE environment, but other than the specific management of the SE function, are not considered to be part of SE. Examples include system construction, manufacturing, funding, and general management. This is reflected in the International Council on Systems Engineering (INCOSE) top-level definition of systems engineering as, "A transdisciplinary and integrative approach to enable the successful realization, use, and retirement of engineered systems, using systems principles and concepts, and scientific, technological, and management methods" (Fellows 2019). Although SE can *enable* the realization of a successful system, if an activity that is outside the scope of SE, such as manufacturing, is poorly managed and executed, SE cannot *ensure* a successful realization.

A convenient way to define the scope of SE within engineering and management is to develop a Venn diagram. Figure 3 shows the relationship between SE, system implementation, and project/systems management. Activities, such as analyzing alternative methods for production, testing, and operations, are part of SE planning and analysis functions. Such activities as production line equipment ordering and installation, and its use in manufacturing, while still important SE environment considerations, stand outside the SE boundary. Note that as defined in Figure 3, system implementation engineering also includes the software production aspects of system implementation. Software engineering, then, is not considered a subset of SE.

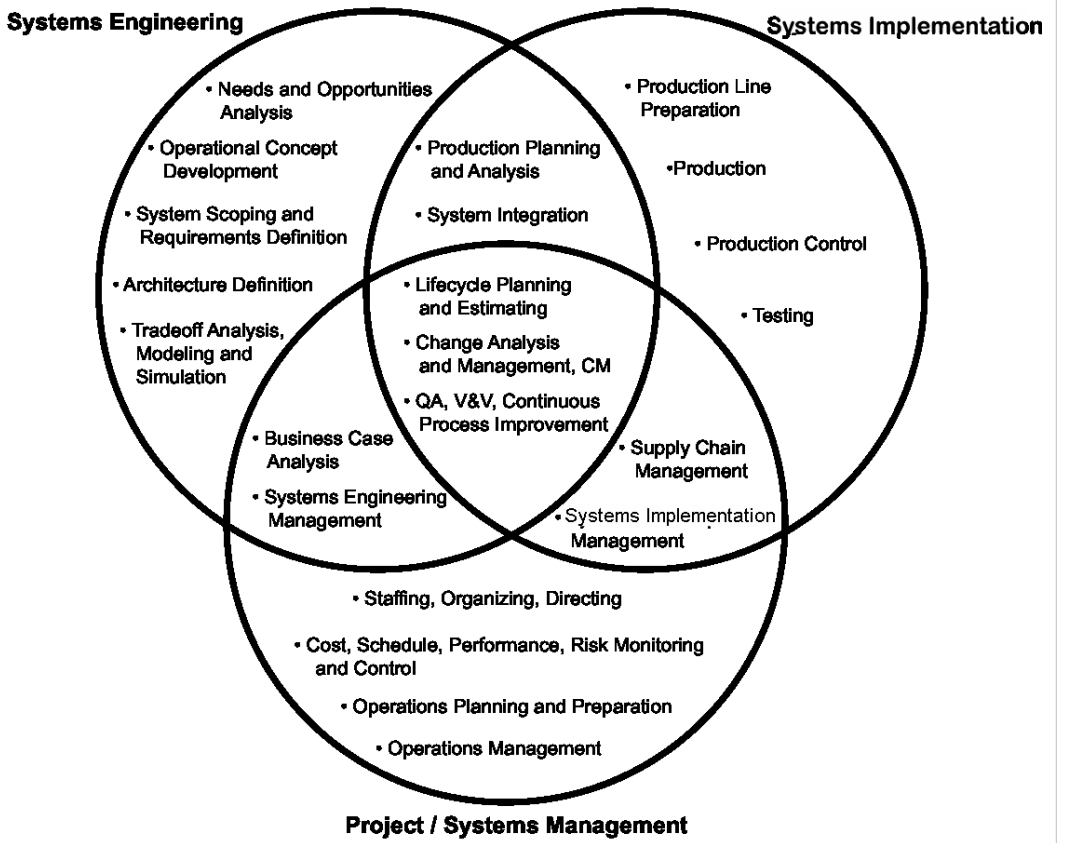

Figure 3. System Boundaries of Systems Engineering, Systems Implementation, and Project/Systems Management. (SEBoK Original)

Traditional definitions of SE have emphasized sequential performance of SE activities, e.g., "documenting requirements, then proceeding with design synthesis …" (INCOSE 2012).Originally, the SEBoK authors & editors departed from tradition to emphasize the inevitable intertwining of system requirements definition and system design in the following revised definition of SE:

> *Systems Engineering (SE) is an interdisciplinary approach and means to enable the realization of successful systems. It focuses on holistically and concurrently understanding stakeholder needs; exploring opportunities; documenting requirements; and synthesizing, verifying, validating, and evolving solutions while considering the complete problem, from system concept exploration through system disposal.* (INCOSE 2012, modified.)

More recently, the INCOSE Fellows have offered an updated definition of SE that has been adopted as the official INCOSE definition:

> *A transdisciplinary and integrative approach to enable the successful realization, use, and retirement of engineered systems, using systems principles and concepts, and scientific, technological, and management methods*.

Part 3: Systems Engineering and Management elaborates on the definition above to flesh out the scope of SE more fully.

Systems Engineering and Engineered Systems Project Life Cycle Context

SE is performed as part of a life cycle approach. Figure 2 summarizes the main agents, activities, and artifacts involved in the life cycle of SE, in the context of a project to create and evolve an engineered system.

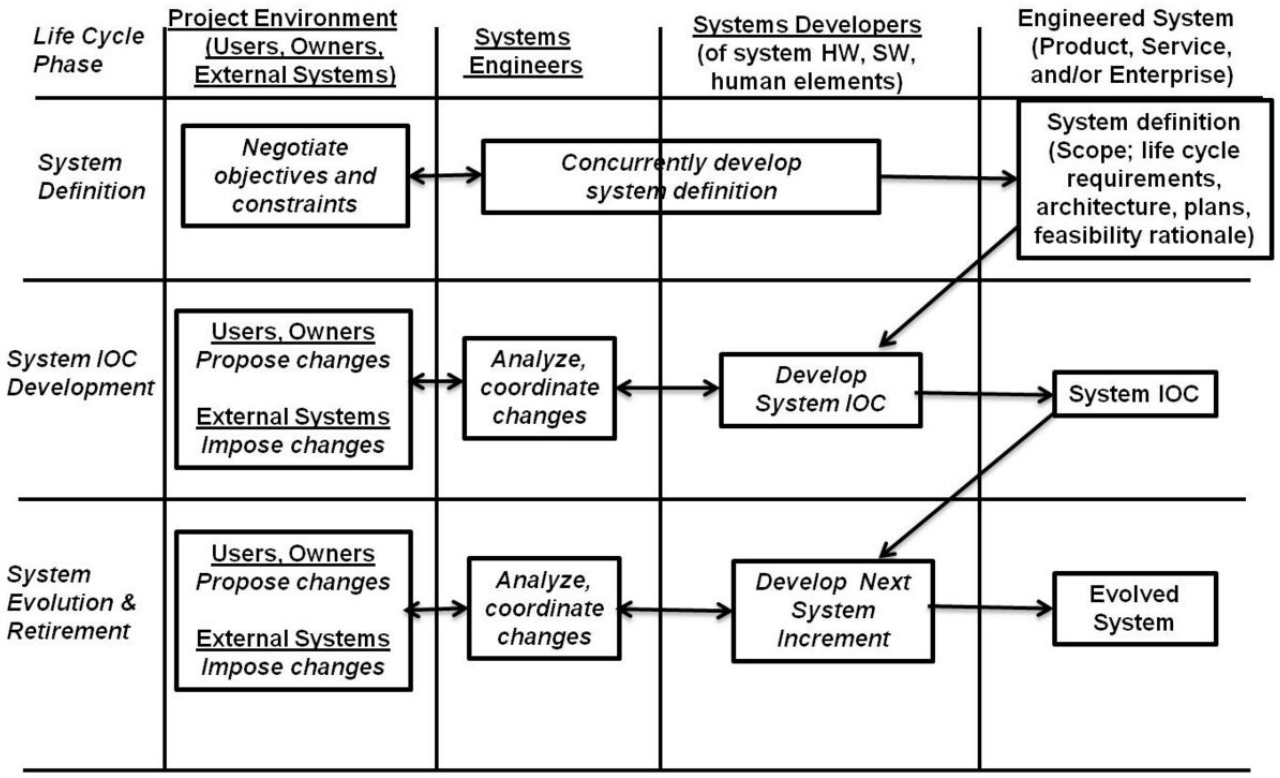

Figure 2. SE and Engineered System Project Life Cycle Context: Related Agents, Activities, and Artifacts. (SEBoK Original)

For each primary project life cycle phase, we see activities being performed by primary agents, changing the state of the ES.

- Primary project life cycle phases appear in the leftmost column. They are system definition, system initial operational capability (IOC) development, and system evolution and retirement.
- Primary agents appear in the three inner columns of the top row. They are systems engineers, systems developers, and primary project-external bodies (users, owners, external systems) which constitute the project environment.
- The ES, which appears in the rightmost column, may be a product, a service, and/or an enterprise.

In each row:

- boxes in each inner column show activities being performed by the agent listed in the top row of that column
- the resulting artifacts appear in the rightmost box.

Arrows indicate dependencies: an arrow from box A to box B means that the successful outcome of box B depends on the successful outcome of box A. Two-headed arrows indicate two-way dependencies: an arrow that points both from box A to box B and from box B to box A means that the successful outcome of each box depends on the successful outcome of the other.

For example, consider how the inevitable changes that arise during system development and evolution are handled:

- One box shows that the system's users and owners may propose changes.
- The changes must be negotiated with the systems developers, who are shown in a second box.
- The negotiations are mediated by systems engineers, who are shown in a third box in between the first two.
- Since the proposed changes run from left to right and the counter-proposals run from right to left, all three boxes are connected by two-headed arrows. This reflects the two-way dependencies of the negotiation.

An agent-activity-artifact diagram like Figure 1 can be used to capture complex interactions. Taking a more detailed view of the present example demonstrates that:

- The system's users and owners (stakeholders) propose changes to respond to competitive threats or opportunities, or to adapt to changes imposed by independently evolving external systems, such as Commercial-off-the-Shelf (COTS) products, cloud services, or supply chain enablers.
- Negotiation among these stakeholders and the system developers follows, mediated by the SEs.
- The role of the SEs is to analyze the relative costs and benefits of alternative change proposals and synthesize mutually satisfactory solutions.

Fundamentals for Digital Engineering

- Lead Authors:
- Emiliya Suprun and Sondoss Elsawah

-

The world has witnessed exponential growth in technological advancement in recent years, and systems engineering (SE) is no exception. SE is transforming the way we design, analyze, and manage complex systems. This transformational change leverages the use of advanced technologies such as Artificial Intelligence (AI), Big Data, and Internet of Things (IoT). However, the evolution of SE goes well beyond just technology advancements. This chapter discusses digital engineering (DE) as a systemic intervention, a holistic approach to SE transformation that involves people, processes, data, and technology.

INCOSE Vision 2035: Transforming SE

The INCOSE Vision 2035 statement (INCOSE 2021) provides insights into the global context for SE, highlighting key trends and influencing factors expected to drive changes in the practice of SE. Some of the principal takeaways include but are not limited to the impacts of digital transformation:

- Digital transformation, sustainability, smart systems and complexity growth, and advancements in modeling, simulation, and visualization are trends that impact enterprise competitiveness.
- The future SE will leverage digital transformation in its tools and methods and move towards a fully model-based SE environment.
- The changing nature of systems includes more embedded and application software, increasing amounts of data to process, and cyber-physical systems.
- The systems of the future will be engineered by an evolving, diverse workforce reshaped by digital transformation and systems of systems.
- Data science techniques will be infused into the SE practice, with trusted data being managed as a critical asset.
- Digital technology, including the broader application of AI, enables the transformation of how enterprises capture, reuse, exploit, and protect knowledge through digital representation and semantic integration of all information.
- Evolving digital ecosystems will enable automation and autonomy to perform increasingly complex tasks.

All engineering disciplines today have evolved, and modern SE needs to be supported by large amounts of data. This requires the transformation of SE practices to DE in which technological innovations are assembled to allow for an integrated digital approach that supports life cycle activities and develops a culture among stakeholders of working more efficiently and effectively (DoD 2018). DE is not a destination but a journey towards the digital transformation of engineering and enterprises. This journey requires a paradigm shift from a traditional paper-based SE to a more integrated approach that leverages digital technology to accelerate the formalization and integration of knowledge, fostering collaboration and adopting a more agile approach to SE.

What is DE?

DE provides an integrated digital approach that uses authoritative sources of systems data and models as a continuum across disciplines to support lifecycle activities from concept through disposal (DoD, 2018). ABAB (2021) defines DE as a collaborative way of working, using digital processes to enable more productive methods of planning, designing, constructing, operating, and maintaining assets. Collaboration with suppliers and partners is improved through DE, reducing the risk of errors and delays. DE is reshaping the landscape of how capabilities, assets and projects are designed and managed across many industries, including defense, transportation, construction, healthcare delivery, and other sectors. Examples include:

- In the defense sector, DE enables the development of innovative weapon systems, reduction in acquisition timelines and improvement of the force's readiness (Zimmerman et al. 2019).
- In transportation, DE improves the design and optimization of infrastructure systems, such as roads, bridges, and airports, to improve safety and efficiency (Wu et al. 2022). DE drives the improvement of the resilience of critical infrastructure systems, such as power grids, water systems, and transportation networks (Suprun et al. 2022).
- In construction, DE enables the design and construction of smarter and more sustainable buildings and infrastructure and the reduction of construction costs and waste (Opoku et al. 2021).
- In healthcare, DE enables development of new medical devices, optimization of hospital operations, and improvement in patient outcomes (Awad et al. 2021). The list goes on.

DE as a Systemic Intervention in Its Own Right

DE is underpinned by the view of enterprises as socio-cultural-technical systems (Sony & Naik, 2020). DE is a systemic intervention that comprises four fundamental components: Why, What, Who and How. These components work together to enable fundamental shifts in organizational culture, practices, and technologies to achieve enterprise digital transformation. Figure 1 provides a holistic view of the dimensions and elements that make the DE intervention.

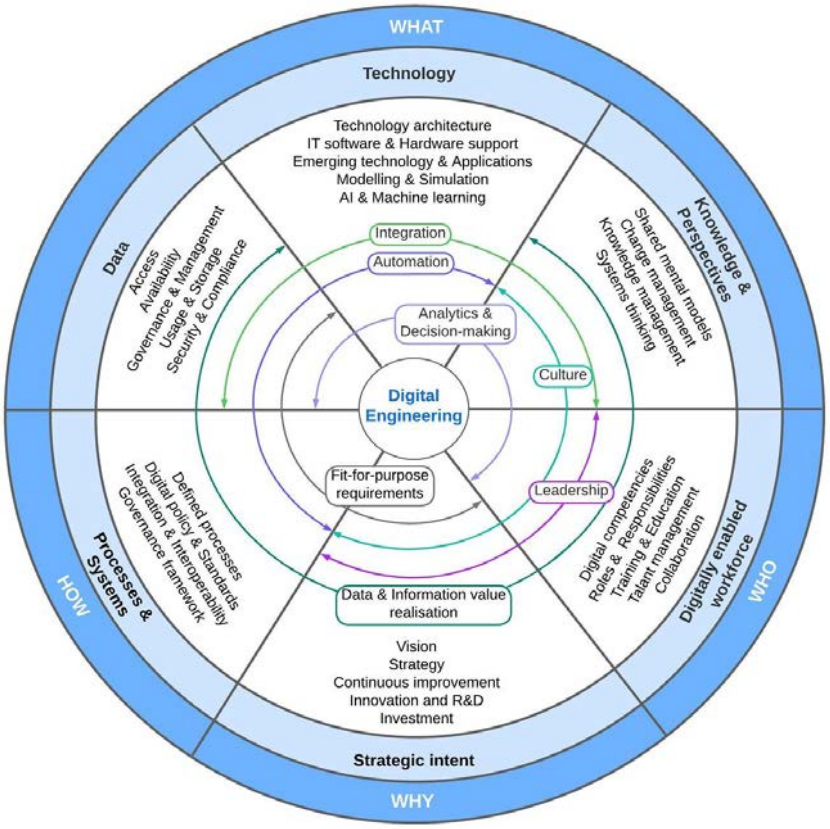

Figure 1. Digital Engineering Systemic Framework

Why: Strategic Intent

The *why* component is critical for establishing the goals and objectives of the DE initiative, as well as for ensuring that it aligns with the broader organizational strategy. DE is not exclusively about technology but the fact that technology enables organizations to transform their business operations and systems and create better-informed decisions around their organizational objectives and strategy.

As part of the process, the immediate targets of transforming SE practices include the digitalization of engineering artifacts, information, and model sharing, while the long-term strategic vision is focused on aligning investments into technological innovations and advanced engineering practices with organizational goals and objectives (Huang, 2020). The organizational view of digital transformation opportunities and innovation should be considered as part of a more extensive continuous improvement process.

A clear DE strategy provides a roadmap for digital transformation, outlining the steps needed to achieve organizational outcomes. They should also consider the organization's culture and how DE transformation will impact the workforce as well as its existing systems and processes. A successful strategy involves stakeholder collaboration to ensure buy-in and alignment with the organization's goals and leadership development. DoD DE Strategy (DoD 2018) identifies the following goals that could be applied to DE activities: (i) model use for decision-making; (ii) developing the authoritative source of truth (AST); (iii) enhancing technological innovation; (iv) establishing collaborative environments; and (v) transforming the workforce and cultural.

A systemic approach to DE drives a shift from a technology-focused acquisition approach to a whole ecosystem view that supports all enablers for genuine transformation, including workforce readiness and awareness of the legal and policy environment. Moreover, the strategic view on DE allows organizations to realize the value of data and information. Industries must collectively recognize the importance of valuing and managing data and information as critical assets.

Who: Digitally Enabled Workforce

The *who* component of DE focuses on the workforce. This component is critical for ensuring industries have the necessary skills and capabilities to embark on the DE journey. It involves identifying the skills, roles, responsibilities, and capabilities needed for the successful digital transformation of engineering and enterprises. It is essential to have a digitally enabled workforce trained and capable of using technological innovation to effectively leverage digital tools and methods.

DE requires a new comprehensive set of skills and competencies beyond traditional SE and IT. It requires a combination of technical and specific data management expertise, such as modeling and simulation, data analytics, AI, and cybersecurity, as well as soft skills, such as communication, collaboration, and leadership. The DE competency framework developed by Hutchison and Tao (2022) identifies the foundational digital competencies: (i) digital literacy; (ii) DE value proposition; (iii) DoD Policy/Guidance; (iv) decision-making; (v) software literacy.

Social and cultural aspects of DE also include the need for a shift in mindset and culture. DE requires a more collaborative agile approach to design, develop, and deploy complex systems and a willingness to adapt and embrace change. It also requires a culture of innovation, continuous improvement and learning as technologies and tools evolve rapidly. The growing worldwide demand for digital and systems engineers exceeds the available supply (INCOSE 2021). Many enterprises initiate internal in-house training programs to develop their workforce further. Nevertheless, there is a need for training and education programs and a life-long learning pipeline that empower more system engineers with strong multi- and transdisciplinary competencies, including digital, business, leadership and systems thinking, needed to enable collaboration across a broad range of the engineering and management workforce globally.

What: Data, Technology, and Knowledge and Perspectives

The *what* component captures dimensions of integration, being data, technology, and knowledge and perspectives. SE faces a significant obstacle today due to the extensive fragmentation among the engineering tools and data landscape (INCOSE 2021). In DE, the use of common integrated models helps overcome these challenges. Integration across different tools, technological solutions and data is becoming a focus for enabling collaboration, analytics, and data-informed decision-making. Integration also ensures that the data generated by different tools are standardized and can be seamlessly shared across different engineering disciplines.

Data is at the heart of DE, and enterprises need to invest in the capabilities for seamless collection, management, and analysis of data to support their digital transformation. Real-time data can improve how complex systems and assets are operated, enable informed decision-making, and allow better responses to disruptions, failures, and environmental concerns. Nevertheless, collecting the trusted data alone is insufficient to improve SE practices. The key is to support an integrated approach enabling the use of high-quality data, security, privacy, and accessibility in a form that allows sharing, visualization, and analysis. For the systems and assets to be managed efficiently, it is crucial to enable consistent, informed decision-making that relies on high-quality, robust data. An organization's insights are only as good as its data. In other words, the value maximization from the physical system requires the value maximization from the data and information. Valuing and managing data and information as critical assets allow a fundamental shift towards data-driven decision-making built on a 'digital by default' culture.

Knowledge is another critical enterprise asset. Both data and knowledge must be managed appropriately for an enterprise to continue to learn and advance. The knowledge and perspectives component of DE encompasses the importance of understanding and sharing common mental models across stakeholders and establishing a shared understanding of DE. Failure to address the underlying cultural shift, a change in mindset, and a new way of thinking will result in "putting a new coat of technological paint over the same crumbling organizational walls" (Forsythe & Rafoth 2022). Hence, DE must be approached as a cultural transformation, where stakeholders across the enterprise are encouraged to adopt new ways of thinking and working together. This requires a top-down commitment to the new approach and investment in training, education, and tools to enable all stakeholders to understand and work within the new paradigm. This shift in mindset and culture can be difficult and requires leadership to drive the change (Laskey et al. 2021).

The technology component is critical for ensuring organizations have the infrastructure, tools, and platforms to support DE. Technology transforms how enterprises capture, reuse, exploit, and protect knowledge through digital representation and semantic integration of all information. Evolving technology, including digital twins, modeling and simulation tools, and data analytics and visualization tools with the broader application of AI, ML, and IoT, will enable automation and autonomy to perform increasingly complex tasks, providing further opportunities for humans to add value through innovation.

The key shift enabled by DE as an integrated approach is a move to collaborative data-driven problem-solving practices. This drives culture transformation and organizational commitment to a 'single source of truth' approach to decision-making.

How: Processes and Systems

The *how* component of DE focuses on processes and systems. As the future of SE, DE is model-based, leveraging next-generation modeling and simulation powered by global digital transformation (INCOSE 2021). The right processes and systems in place provide consistent digital transformation to deliver value throughout system elements, disciplines, the life cycle, and the enterprise. Defined processes and structured procedures ensure that information fits its intended purpose and can be shared and reused. Moreover, organizations must develop a systematic approach to integrate DE tools and techniques into their existing processes and systems to allow for a seamless flow of data, information, knowledge, and expertise.

DE opens new opportunities but also introduces new integration challenges. One of the critical challenges is the need for interoperability and standardization. Standardized or commonly shared digital representation forms, semantics, and vocabulary are critical for sharing digitalized engineering artefacts, especially digital models.

The core concept in DE is using digital models integrated with simulation, multi-disciplinary analysis, and immersive visualization environments. In other words, one of DE's key technical aspects is using model-based systems engineering (MBSE). MBSE provides a common language and framework for communicating and managing system requirements, design, and implementation. MBSE also enables system designers and engineers to simulate and test system behavior in a virtual environment, reducing the need for physical prototypes. The transformation to DE is happening step by step, and the evolution goes beyond just MBSE. While MBSE is a critical component of DE, it is only one part of a more significant shift towards digital transformation (McDermott et al. 2022). DE involves a fundamental shift in mindset and requires organizations to embrace a more collaborative approach to problem-solving, with stakeholders from across the organization working together to develop more efficient, effective, and responsive solutions to rapidly changing industry demands.

The key shift enabled by DE processes and systems is a move towards the end-to-end digital representation of the enterprise to address long-standing challenges associated with complexity, uncertainty, and rapid change in deploying and using systems. DE also drives a shift from confined and ad-hoc use of models for immediate benefits to continuous and coherent use of models across the lifecycle to drive and accelerate organizational outcomes.

Conclusions

DE goes beyond using specific software tools and models. It builds upon the principles of SE, leveraging technologies and modeling and simulation methods to enhance data-driven decision-making and optimize system performance. DE is about creating a culture of innovation, collaborative problem-solving, and continuous improvement, changing how we connect, understand, and navigate our environments.

Economic Value of Systems Engineering

-

The Increasing Value of Systems Engineering

With traditional projects, such as railroads, reservoirs, and refrigerators, a systems engineer faced a self-contained system that typically had relatively stable requirements, a sound scientific base, and numerous previous precedents. As most modern systems become parts within one or more evolving systems of systems (SoS), the performance of effective SE now takes on an ever-higher economic value, as the systems feature a rapidly increasing scale, dynamism, interdependence, human-intensiveness, number of sources of vulnerability, and novelty.

This is corroborated by the implementation examples in Part 7. Shortfalls in SE lead to either cancellation of already expensive systems or even more expensive systems in terms of total cost of ownership or loss of human life. Part 7 presents the problems in the United States Federal Aviation Administration (FAA) Advanced Automation System (AAS), United States Federal Bureau of Investigation (FBI) Virtual Case File System, the Hubble Space Telescope Case Study, and the Therac-25 medical linear accelerator.

On the other hand, the Global Positioning System (GPS), Miniature Seeker Technology Integration Project (MSTI), and Next Generation Medical Infusion Pump Project all demonstrate that investment in thorough SE results in highly cost-effective systems. Figure 1 summarizes the analyses data by Werner Gruhl, which relates investment levels in SE to cost overruns of the United States National Aeronautics and Space Administration (NASA) projects (Stutzke 2005). The results indicate that there is a general correlation between the amount invested in SE within a program and cost overruns, demonstrating the critical role of properly allocating SE resources.

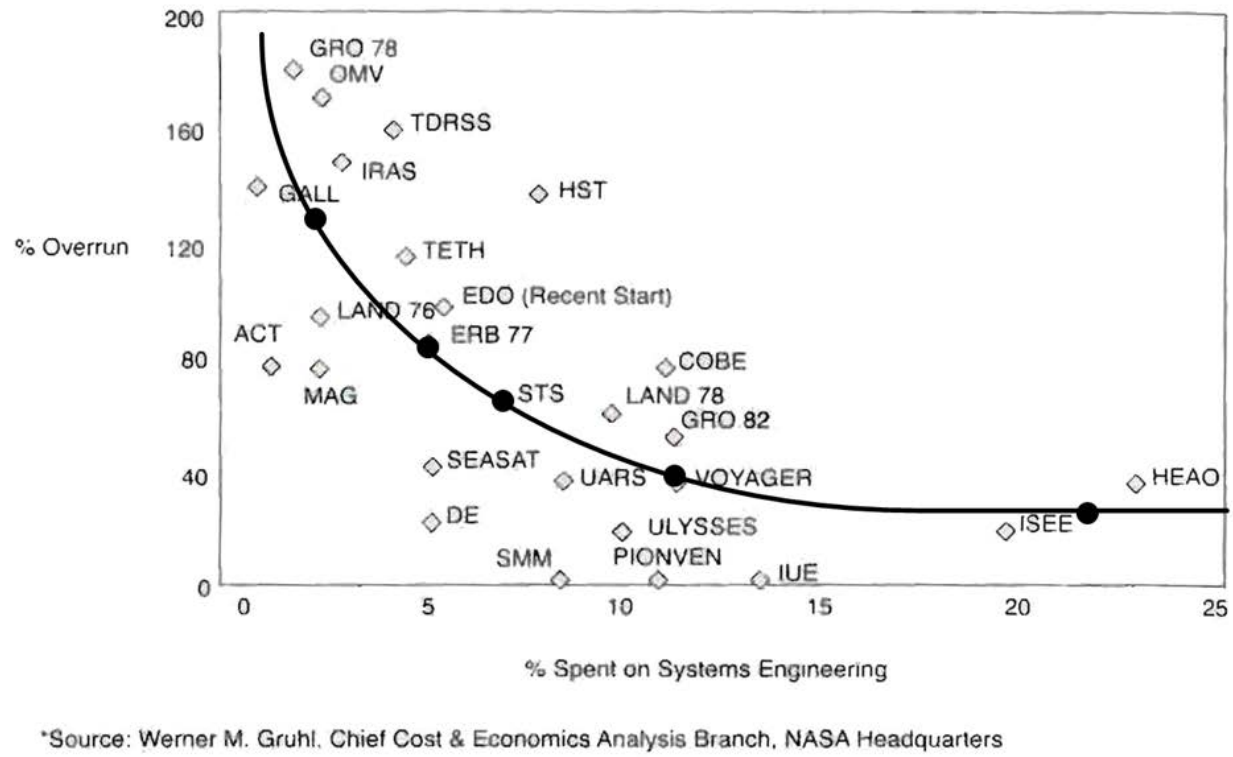

Figure 1. Relation of SE Investments to NASA Program Cost Overruns (Stutzke 2005). Released by NASA HDQRT/Gruhl.

Further Quantitative Evidence of the Value of Systems Engineering

Analysis of the effects of shortfalls in systems architecture and risk resolution (the results of insufficient SE) for software-intensive systems in the 161-project Constructive Cost Model II (COCOMO™ II) database shows a statistically significant increase in rework costs as a function of project size measured in source lines of code (SLOC): averages of 18% rework for ten-thousand-SLOC projects and 91% rework for ten-million-SLOC projects. This data has influenced many major system projects to reconsider initial underinvestment in SE (e.g., Boehm et al. 2004), as well as to address "how much SE is enough" by balancing the risks of under-investing in SE against those of over-investing (often called "analysis paralysis"), as shown in Figure 2 (Boehm, Valerdi, and Honour 2008).

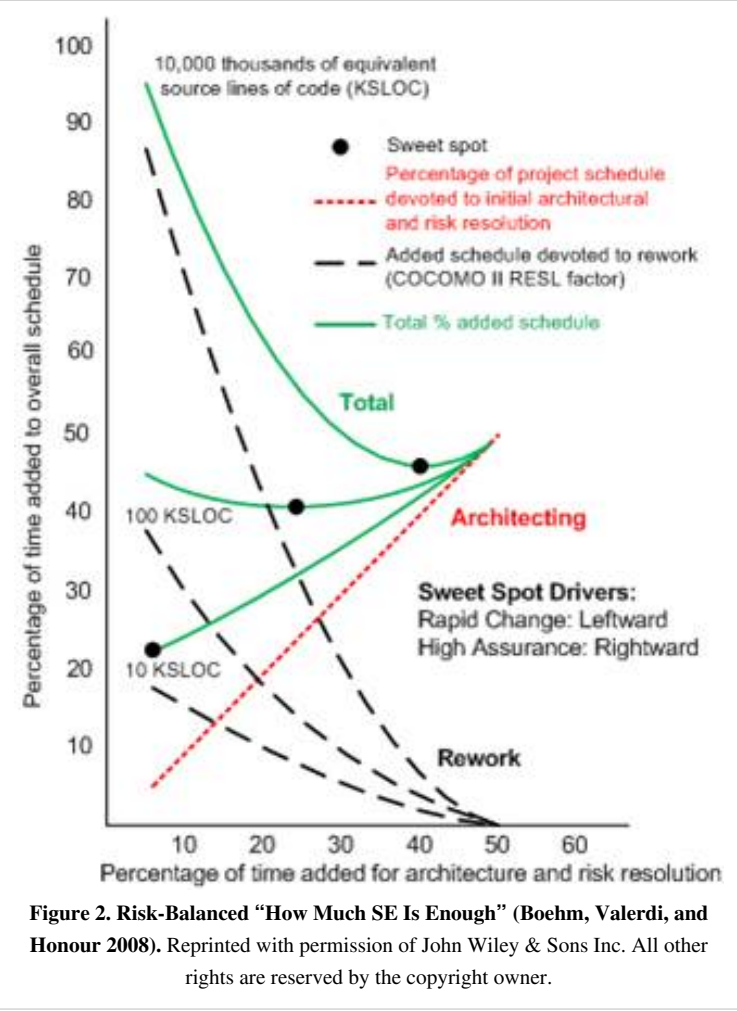

Figure 2. Risk-Balanced "How Much SE Is Enough" (Boehm, Valerdi, and Honour 2008). Reprinted with permission of John Wiley & Sons Inc. All other rights are reserved by the copyright owner.

Typically, small projects can quickly compensate for neglected SE interface definition and risk resolution; however, as projects grow larger and have more independently-developed components, the cost of late rework negates any savings in reduced SE effort. Additionally, medium-sized projects have relatively flat operating regions, while very large projects pay extremely large penalties for neglecting thorough SE. Extensive surveys and case study analyses corroborate these results.

Survey data on software cost and schedule overruns in *My Life Is Failure: 100 Things You Should Know to Be a Better Project Leader* (Johnson 2006) indicates that the primary sources of the roughly 50% of commercial projects with serious "software overruns" are the result of shortfalls in SE (lack of user input, incomplete requirements, unrealistic expectations, unclear objectives, and unrealistic schedules). The extensive survey of 46 government-contracted industry projects conducted by the Software Engineering Institute (SEI)/National Defense Industrial Association (NDIA) illustrated a strong correlation between higher project SE capability and higher project performance (Elm et al. 2007). Ongoing research that combined project data and survey data reported in

“Toward an Understanding of The Value of SE” (Honour 2003) and “Effective Characterization Parameters for Measuring SE” (Honour 2010) has provided additional evidence as to the economic value of SE and further insights on critical factors that affect SE success.

```
The Constructive Systems Engineering Cost Model (COSYSMO), a calibrated
 model for determining “how much SE is enough,” has been developed and
is discussed in (Valerdi 2008). It estimates the number of
person-months that a project needs for SE as a function of system size
(i.e., requirements, interfaces, algorithms, and operational
scenarios), modified by 14 factors (i.e., requirements understanding,
technology risk, personnel experience, etc.), which dictates the amount
 of SE effort needed.  Other economic considerations of SE include the
costs and benefits of reuse (Wang, Valerdi and Fortune 2010), the
management of SE assets across product lines (Fortune and Valerdi
2013), the impact of SE on project risk (Madachy and Valerdi 2010), and
 the role of requirements volatility on SE effort (Pena and Valerdi
2010).
```

A Brief History of Systems Engineering

- Lead Author:
- Robert Cloutier
- Contributing Author:
- Michael Pennotti

-

While many will attribute systems thinking to great accomplishments such as the Egyptian pyramids, Incan ziggurats, and the Roman aqueduct system, this article will pick up with the early mentions of systems engineering as a discipline. One only has to look to find a healthy body of works on the history of systems engineering. Many of those articles are cited in the References section below. The purpose of this article is to highlight the evolution of both the practice and definition of systems engineering as it emerged in the 20th century.

The Forties and Fifties (1940-1959)

During World War II, systems engineering began to emerge to deal with the myriad new technologies developed in support of the war effort. For example, an analysis of the RAF Fighter Command C2 System, which was crucial to the United Kingdom's prevailing in the 1940 Battle of Britain, performed by Derek Hitchens in 2005, concluded that its design represented "systems engineering of the highest caliber, even though that term had not yet been invented". (Hitchins 2005)

The first known use of the term "systems engineering" was in a March 1950 presentation to the Royal Society of London by Mervin J. Kelly, then Executive Vice President of Bell Telephone Laboratories. The transcript of Kelly's presentation entitled, "The Bell Telephone Laboratories - An Example of an Institute of Creative Technology", was published in the Proceedings of the Royal Society later that year. (Kelly 1950) In it, Kelly discussed the progress of Bell Labs over the first half of the twentieth century. He stated that the organization "grew in size and matured in the scope and character of its work during the period of rapid expansion in research in the physical sciences". From there, he went on to describe the organization of their work. The first organizational heading was Research and Fundamental Development. The second was 'Systems Engineering,' at the same level of importance as the research and development departments. Kelly described the responsibility of the systems engineering organization as "… the determination of new specific systems and facilities development projects – their operational and economic

objectives and the broad technical plan to be followed. 'Systems engineering' controls and guides the use of the new knowledge obtained from the research and fundamental development programs in the creation of new telephone services and the improvement and lowering of cost of services already established…it attempts to ensure that the technical objectives of the development projects undertaken can be realized within the framework of the new knowledge available in the reservoir and present engineering practice."

The first published paper specifically about systems engineering appeared in 1956. In it, Kenneth Schlager of General Motors wrote, "Increased complexity in the fields of communications, instruments, computation, and control has led to an emphasis on the field of systems engineering." He went on to say, "Though engineers with system functions can be found in almost all phases of the modern electronics and aircraft industries, there seems to be no commonly agreed upon definition of the term "systems engineering." Nevertheless, he said, "the rise of systems engineering as a separate field has resulted in some organizational changes in the engineering departments of many companies… "typical instance is that of a systems engineering group which has established itself on an equal level with other electrical and mechanical design groups in the engineering department." (Schlager 1956)

E.W. Engstrom grew up in the Radio Corporation of America (RCA) Laboratories. He became the president and CEO of RCA in 1961 and 1966 respectively. However, in 1957 he published another early paper on systems engineering in Electrical Engineering. Engstrom explained the concept of systems engineering in terms of its evolution and characteristics and described the engineering of a color television system and of a specific weapons system to illustrate its application. He stated [that "the task of adapting our increasingly complex devices and techniques to the requirements and limitations of the people who must use them has presented modern engineering with its greatest challenge. To meet this challenge, we have come to rely increasingly during recent years upon the comprehensive and logical concept known as systems engineering. He defined only two requirements for successful systems engineering. "First, a determination of the objective that is to be reached; and second, a thorough consideration of all the factors that bear upon the possibility of reaching the objective and the relationships among these factors." (Engstrom 1957)

The first textbook on the subject of systems engineering was Systems Engineering: An Introduction to the Design of Large-Scale Systems written by Goode and Mahol. It sold for $10 when published in 1957. In it, the authors stated, "this book develops no general theory. It presents experience, the parts and the pieces, and the relationships among them; occasionally, in a small area, it attempts to tie several parts together with a general observation". (Goode and Machol 1957)

The Sixties and Seventies (1960-1979)

Arthur Hall, who also worked for Bell Telephone Laboratories, taught one of the earliest Systems Engineering courses at MIT. In his book "A Methodology for Systems Engineering", Hall identified five traits of the ideal systems engineer (1962):

1. an affinity for the systems
2. faculty of judgment
3. Creativity
4. facility in human relations, and
5. facility for expression

He also wrote: "Systems engineering is most effectively conceived of as a process that starts with the detection of a problem and continues through problem definition, planning and designing of a system, manufacturing or other implementing section, its use, and finally on to its obsolescence. Further, systems engineering is not a matter of tools alone; it is a careful coordination of process, tools, and people."

Another interesting historical description of systems engineering appeared in a 1967 report to the Committee on Science and Astronautics of the U.S. House of Representatives. In the report, Hendrik Bode of Bell Laboratories wrote: "…the systems engineer resembles an architect, who must generally have adequate substantive knowledge of

building materials, construction methods, and so on, to ply his trade. Like architecture, systems engineering is in some ways an art as well as a branch of engineering. Thus, aesthetic criteria are appropriate for it also. For example, such essentially aesthetic ideas as balance, proportion, proper relation of means to ends, and economy of means are all relevant in a systems-engineering discussion. Many of these ideas develop best through experience." (Panel on Applied Science and Technological Progress 1967)

Several common themes emerge in the early references to systems engineering as practiced during its first three decades:

- Systems engineers were deeply immersed in, and knowledgeable of, their application domains,
- Their analysis relied on domain-specific science, math, and engineering,
- The systems engineering effort transcended multiple technical and non-technical disciplines (e.g. including economics, psychology, and operations). It was, in fact, "transdisciplinary" from its inception, though that term has only been applied recently and
- As practiced, systems engineering was informal in nature, essentially the application of systems thinking to the engineering of systems.

Despite the lack of formal structure during these early decades, systems engineering played an essential role in the achievement of perhaps the greatest technical accomplishment of that era, the landing of a man on the moon and his safe return to the earth in July of 1969.

Coincidentally, the same month as the Apollo landing saw the introduction of the first formal systems engineering process. Military Standard (MIL-STD)-499: *System Engineering Management*, was published by the U.S. Air Force. (1969) Later extended to the entire DoD, the intent of this Mil-Std was to provide program managers and contractors with guidance for managing the systems engineering process. Later, in 1974, the DoD updated their guidance with MIL-STD-499A. It too covered the process but added guidelines for the Systems Engineering Management Plan (SEMP) and task statements that could be selectively applied to a DoD acquisition program.

The Eighties and Nineties (1980-1999)

The National Council on Systems Engineering (NCOSE) grew out of the need for formally trained systems engineers. Meetings between industry and academia began in 1989 and continued through 1991. Notable names included Jeffrey Grady (GD), Dr. David Sworder (UCSD), Dr. Brian Mar (U of Washington), Dr. Terry Bahill and Dr. Ron Askin (U of Arizona), and Gerald Chasko (DSMC Regional Director). The group grew to include industry and DoD representatives from the USAF, TRW, Lockheed, Martin Marietta, MacDonnell Douglas, Aerospace Corp, Bechtel, TI, Boeing, Unisys, IBM and many others. In 1989, Dr. Brian Mar took the lead to begin the International Council on Systems Engineering and is recognized as the Father of INCOSE. (Grady, 2013).

Hughes hosted the January 1992 business meeting in Los Angeles with NCOSE, now a formally incorporated organization (Honour, 1998). Later, this organization would change its name and become known as the International Council on Systems Engineering. The first edition "Systems Engineering", the journal for NCOSE was published in July/September 1994.

In 1995, the NASA Systems Engineering Handbook (NASA/SP-6105) was published to bring the fundamental concepts and techniques of systems engineering to the National Aeronautics and Space Administration (NASA) personnel in a way that recognized the nature of NASA systems and the NASA environment.

Finally, version 1 of INCOSE's *Systems Engineering Handbook* first appeared in 1997.

21st Century

In 2005, the International Standards Organization (ISO) published their first standard defining systems engineering application and management. The purpose of this ISO standard was to define the interdisciplinary tasks which are required throughout a system's life cycle to transform customer needs, requirements and constraints into a system solution. In addition, it defines the entire systems engineering lifecycle. A number of related standards followed, to include ISO/IEC TR 24748-1:2010, 15288, and 12207.

There are a many great articles documenting a more thorough history of systems engineering that are found in the References section of this brief article.

Systems Engineering: Historic and Future Challenges

-

Humans have faced increasingly complex challenges and have had to think systematically and holistically in order to produce successful responses to these challenges. From these responses, generalists have developed generic principles and practices for replicating success. Some of these principles and practices have contributed to the evolution of systems engineering as a discipline.

Historical Perspective

Some of the earliest relevant challenges were in organizing cities. Emerging cities relied on functions such as storing grain and emergency supplies, defending the stores and the city, supporting transportation and trade, providing a water supply, and accommodating palaces, citadels, afterlife preparations, and temples. The considerable holistic planning and organizational skills required to realize these functions were independently developed in the Middle East, Egypt, Asia, and Latin America, as described in Lewis Mumford's *The City in History* (Mumford 1961).

Megacities, and mobile cities for military operations, such as those present in the Roman Empire, emerged next, bringing another wave of challenges and responses. These also spawned generalists and their ideological works, such as Vitruvius and his *Ten Books on Architecture* (Vitruvius: Morgan transl. 1960). "Architecture" in Rome meant not just buildings, but also aqueducts, central heating, surveying, landscaping, and overall planning of cities.

The Industrial Revolution brought another wave of challenges and responses. In the nineteenth century, new holistic thinking and planning went into creating and sustaining transportation systems, including canal, railroad, and metropolitan transit. General treatises, such as *The Economic Theory of the Location of Railroads* (Wellington 1887), appeared in this period. The early twentieth century saw large-scale industrial enterprise engineering, such as the Ford automotive assembly plants, along with treatises like *The Principles of Scientific Management* (Taylor 1911).

The Second World War presented challenges around the complexities of real-time command and control of extremely large multinational land, sea, and air forces and their associated logistics and intelligence functions. The postwar period brought the Cold War and Russian space achievements. The U.S. and its allies responded to these challenges by investing heavily in researching and developing principles, methods, processes, and tools for military defense systems, complemented by initiatives addressing industrial and other governmental systems. Landmark results included the codification of operations research and SE in *Introduction to Operations Research* (Churchman et. al 1957), Warfield (1956), and Goode-Machol (1957) and the Rand Corporation approach as seen in *Efficiency in Government Through Systems Analysis* (McKean 1958). In theories of system behavior and SE, we see cybernetics (Weiner 1948), system dynamics (Forrester 1961), general systems theory (Bertalanffy 1968), and mathematical systems engineering theory (Wymore 1977).

Two further sources of challenge began to emerge in the 1960s and accelerated in the 1970s through the 1990s: awareness of the criticality of the human element, and the growth of software functionality in engineered systems.

Concerning awareness of the human element, the response was a reorientation from traditional SE toward “soft” SE approaches. Traditional hardware-oriented SE featured sequential processes, pre-specified requirements, functional-hierarchy architectures, mathematics-based solutions, and single-step system development. A Soft Systems approach to SE is characterized by emergent requirements, concurrent definition of requirements and solutions, combinations of layered service-oriented and functional-hierarchy architectures, heuristics-based solutions, and evolutionary system development. Good examples are societal systems (Warfield 1976), soft systems methodology (Checkland 1981), and systems architecting (Rechtin 1991 and Rechtin-Maier 1997). As with Vitruvius, "architecting" in this sense is not confined to producing blueprints from requirements, but instead extends to concurrent work on operational concepts, requirements, structure, and life cycle planning.

The rise of software as a critical element of systems led to the definition of Software Engineering as a closely related discipline to SE. The Systems Engineering and Software Engineering knowledge area in Part 6: Related Disciplines describes how software engineering applies the principles of SE to the life cycle of computational systems (in which any hardware elements form the platform for software functionality) and of the embedded software elements within physical systems.

Evolution of Systems Engineering Challenges

Since 1990, the rapidly increasing scale, dynamism, and vulnerabilities in the systems being engineered have presented ever-greater challenges. The rapid evolution of communication, computer processing, human interface, mobile power storage and other technologies offers efficient interoperability of net-centric products and services, but brings new sources of system vulnerability and obsolescence as new solutions (clouds, social networks, search engines, geo-location services, recommendation services, and electrical grid and industrial control systems) proliferate and compete with each other.

Similarly, assessing and integrating new technologies with increasing rates of change presents further SE challenges. This is happening in such areas as biotechnology, nanotechnology, and combinations of physical and biological entities, mobile networking, social network technology, cooperative autonomous agent technology, massively parallel data processing, cloud computing, and data mining technology. Ambitious projects to create smart services, smart hospitals, energy grids, and cities are under way. These promise to improve system capabilities and quality of life but carry risks of reliance on immature technologies or on combinations of technologies with incompatible objectives or assumptions. SE is increasingly needed but increasingly challenged in the quest to make future systems scalable, stable, adaptable, and humane.

It is generally recognized that there is no one-size-fits-all life cycle model that works best for these complex system challenges. Many systems engineering practices have evolved in response to this challenge, making use of lean, agile, iterative and evolutionary approaches to provide methods for simultaneously achieving high-effectiveness, high-assurance, resilient, adaptive, and life cycle affordable systems;. The emergence of system of systems (SoS)

approaches have also been introduced, in which independent system elements developed and deployed within their own life cycle are brought together to address mission and enterprise needs.

Creating flexible and tailored life cycles and developing solutions using combinations of engineered systems, each with its own life cycle focus, creates its own challenges of life cycle management and control. In response to this, enterprise systems engineering (ESE) approaches have been developed, which consider the enterprise itself as a system to be engineered. Thus, many of the ambitious smart system projects discussed above are being delivered as a program of managed life cycles synchronized against a top down understanding of enterprise needs. It is important that within these approaches we create the flexibility to allow for bottom-up solutions developed by combining open, interoperable system elements to emerge and be integrated into the evolving solutions.

More recently, emerging technologies such as artificial intelligence, machine learning, deep learning, mechatronics, cyberphysical systems, cybersecurity, Internet of Things (IoT), additive manufacturing, digital thread, Factory 4.0, etc. are challenging approaches to SE.

Many of the challenges above, and the SE response to them, increase the breadth and complexity of the systems information being considered. This increases the need for up to date, authoritative and shared models to support life cycle decisions. This has led to the development and ongoing evolution of model-based systems engineering (MBSE) approaches.

Future Challenges

The INCOSE Systems Engineering Vision 2025 (INCOSE 2014) considers the issues discussed above and from this gives an overview of the likely nature of the systems of the future. This forms the context in which SE will be practiced and give a starting point for considering how SE will need to evolve:

- Future systems will need to respond to an ever growing and diverse spectrum of societal needs in order to create value. Individual engineered system life cycles may still need to respond to an identified stakeholder need and customer time and cost constraint. However, they will also form part of a larger synchronized response to strategic enterprise goals and/or societal challenges. System life cycles will need to be aligned with global trends in industry, economy and society, which will, in turn, influence system needs and expectations.
- Future systems will need to harness the ever-growing body of technology innovations while protecting against unintended consequences. Engineered system products and services need to become smarter, self-organized, sustainable, resource efficient, robust and safe in order to meet stakeholder demands.
- These future systems will need to be engineered by an evolving, diverse workforce which, with increasingly capable tools, can innovate and respond to competitive pressures.

These future challenges change the role of software and people in engineered systems. The Systems Engineering and Software Engineering knowledge area considers the increasing role of software in engineered systems and its impact on SE. In particular, it considers the increasing importance of cyber-physical systems in which technology, software and people play an equally important part in the engineered systems solutions. This requires a SE approach able to understand the impact of different types of technology, and especially the constraints and opportunities of software and human elements, in all aspects of thelife cycle of an engineered system.

All of these challenges, and the SE responses to them, make it even more important that SE continues its transition to a model-based discipline.

The changes needed to meet these challenges will impact the life cycle processes described in Part 3: Systems Engineering and Management and on the knowledge, skills and attitudes of systems engineers and the ways they are organized to work with other disciplines as discussed in Part 5: Enabling Systems Engineering and Part 6: Related Disciplines. The different ways in which SE is applied to different types of system context, as described in Part 4: Applications of SE, will be a particular focus for further evolution to meet these challenges. The Introduction to SE Transformation knowledge area in SEBoK Part 1 describes how SE is beginning to change to meet these challenges.

Systems Engineering and Other Disciplines

-

As discussed in the Scope of the SEBoK article, there are many touch points and overlaps between systems engineering (SE) and other disciplines. Systems engineers should have a basic understanding of the nature of these other disciplines, and often need to understand aspects of another discipline in detail. This article describes the landscape of disciplines that are intertwined with SE. For a closer view of the individual disciplines, see Part 6.

Engineering Disciplines Other than Systems Engineering

Engineering disciplines are mostly component-oriented and value-neutral in their intellectual content (Boehm and Jain 2006). Their underlying laws and equations, such as Ohm's Law, Hooke's Law, Newton's Laws, Maxwell's equations, the Navier-Stokes equations, Knuth's compendia of sorting and searching algorithms, and Fitts's Law of human movement, pertain to performance in a system-of-interest. They do not address how that performance contributes to the value propositions of stakeholders.

In contrast, SE is more holistic than component-oriented, and more stakeholder value-oriented than value-neutral, performance-oriented in its intellectual content. Realizing successful systems requires reasoning with stakeholders about the relative value of alternative realizations, and about the organization of components and people into a system that satisfies the often-conflicting value propositions of stakeholders. Stakeholders who are critical to the system's success include funders, owners, users, operators, maintainers, manufacturers, and safety and pollution regulators.

In some disciplines, the engineer evaluates and integrates design elements into a system that satisfies proxies of value. The wider the scope of the SoI, the broader the set of SE skills the engineer needs.

For example, an aeronautical engineer might integrate mechanical, electrical, fluid, combustion-chemical, software, and cockpit design elements into a system that satisfies proxies of value like flight range, payload capacity, fuel consumption, maneuverability, and cost of production and maintenance. In so doing, the engineer operates partly as a systems engineer. The SoI is the aircraft itself and the engineer applies aircraft-domain expertise.

However, the same engineer could participate in the engineering of passenger services, airport configurations, baggage handling, and local surface transportation options. All of these contribute to the value propositions of success-critical stakeholders. The SoIs are wider, and the engineer needs broader SE knowledge, skills, and abilities to operate as a systems engineer. The aircraft-domain expertise remains needed for effective engineering of the wider systems. As discussed in (Guest 1991), most good systems engineers are "T-shaped" people, with both a working

knowledge of wider-system considerations, and a deep expertise in a relevant domain, such as aeronautical, manufacturing, software, or human factors engineering.

Engineering disciplines that are intertwined with SE include software engineering (SwE), human factors engineering, and industrial engineering. SwE and SE are not just allied disciplines, they are intimately intertwined (Boehm 1994). Most functionality of commercial and government systems is now implemented in software, and software plays a prominent or dominant role in differentiating competing systems in the marketplace. Software is usually prominent in modern systems architectures and is often the "glue" for integrating complex system components.

The scope of SwE includes both software SE and software construction, but does not include hardware SE. Thus, neither SwE nor SE is a subset of the other. See Figure 1 in Scope of the SEBoK. For a definition of the relationship between the SEBoK and the *Guide to the Software Engineering Body of Knowledge (SWEBOK)*, which is published by the Institute of Electrical and Electronics Engineers (IEEE) (Bourque and Fairley 2014), see Systems Engineering and Software Engineering.

Human factors engineering, from micro-ergonomics to macro-ergonomics, is intertwined with SE (Booher 2003; Pew and Mavor 2007). See Human Systems Integration in Part 6.

Industrial engineering overlaps significantly with SE in the industrial domain, but also includes manufacturing and other implementation activities outside of SE. See Systems Engineering and Industrial Engineering in Part 6.

Finally, to field a successful system, a systems engineer may need to know one or more of the many specialty fields in engineering, e.g., security, safety, reliability, availability, and maintainability engineering. Most of these are considered professional disciplines in their own right and many have their own bodies of knowledge. For explanations of how these disciplines relate to SE, overviews of what most systems engineers need to know about them, and references within their bodies of knowledge, see Systems Engineering and Specialty Engineering in Part 6.

Non-Engineering Disciplines

SE is intimately intertwined with two non-technical disciplines: technical management (TM), and procurement and acquisition (also known as acquisition and procurement). TM often falls within the purview of a systems engineer. Many SE textbooks, competency models, and university programs include material about TM. TM is a specialization of project management (PM). SE and PM have significant common content in TM, but neither is a subset of the other. See Figure 1 in the article Scope of the SEBoK. For a definition of the relationship between the SEBoK and the *Guide to the Project Management Body of Knowledge (PMBOK)*, which is published by the Project Management Institute (PMI) (PMI 2013), see Systems Engineering and Project Management in Part 6.

Procurement and acquisition practitioners draw upon SE to determine the scope and overall requirements of the system to be procured or acquired. They then prepare requests for proposals and statements of work, determine evaluation criteria, and design source selection processes. Once a leading source is selected, they decide upon contracting options that encompass payments, reviews, audits, incentive fees, acceptance criteria, procedures, and the nature of deliverables. Finally, they monitor progress with respect to plans (including those for SE), and negotiate and execute changes and corrective actions. Many of these activities amount to specialty disciplines within procurement and acquisition. See the article Related Disciplines in Part 6.

Fundamentals for Future Systems Engineering

- Lead Author:
- Rick Adcock
- Contributing Author:
- Duane Hybertson

-

This article forms part of the Systems Fundamentals knowledge area (KA). It considers future trends in SE and how these might influence the evolution of future fundamentals.

The SEBoK contains a guide to generalized knowledge about the practice of SE. It does not pass judgement on that knowledge. However, it can be useful in some cases to indicate which parts of the knowledge are rooted in existing practice and which point towards the future evolution of SE.

This article provides a sketch of how SE is changing and suggests how these changes may affect the future of systems engineering, the SEBoK, and the foundations in Part 2.

INCOSE Vision

The INCOSE Vision 2025 statement (INCOSE 2014) depicts some future directions in:

Broadening SE Application Domains

- SE relevance and influence will go beyond traditional aerospace and defense systems and extend into the broader realm of engineered, natural and social systems
- SE will be applied more widely to assessments of socio-physical systems in support of policy decisions and other forms of remediation

More Intelligent and Autonomous Systems

- Systems of the future need to become smarter, self-organized, sustainable, resource-efficient, robust and safer
- The number of autonomous vehicles and transportation systems needs to increase
- Systems become more “intelligent” and dominate human-safety critical applications

Theoretical Foundations

- SE will be supported by a more encompassing foundation of theory and sophisticated model-based methods and tools allowing a better understanding of increasingly complex systems and decisions in the face of uncertainty
- Challenge: A core body of systems engineering foundations is defined and taught consistently across academia and forms the basis for systems engineering practice

In this article we will consider how the fundamentals of SE might need to evolve to support this vision.

How will SE Change?

In Engineered Systems, we describe three general contexts in which a SE life cycle can be applied. In a product system context, the outputs of SE focus on the delivery of technological systems. While such systems are designed to be used by people and fit into a wider problem-solving context, this context has been seen as largely fixed and external to SE. The service system context allows SE to consider all aspects of the solution system as part of its responsibility. This is currently seen as a special case of SE application largely focused on software intensive solutions. The enterprise system context offers the potential for a direct application of SE to tackle complex socio-technical problems, by supporting the planning, development and use of combinations of service systems. While this is done, it can be difficult to connect to the product focused life cycles of many SE projects.

The role of the systems engineer has already begun to change somewhat due to the first two of the future trends above. Changes to the scope of SE application and the increased use of software intensive reconfigurable and autonomous solutions will make the service system context the primary focus of most SE life cycles. To enable this, most product systems will need to become more general and configurable, allowing them to be used in a range of service systems as needed. These life cycles are increasingly initiated and managed as part of an enterprise portfolio of related life cycles.

In this evolution of SE, the systems engineer cannot consider as many aspects of the context to be fixed, making the problem and possible solution options more complex and harder to anticipate. This also means the systems engineer has greater freedom to consider solutions which combine existing and new technologies and in which the role of people and autonomous software can be changed to help deliver desired outcomes. For such systems to be successful, they will need to include the ability to change, adapt and grow both in operation and over several iterations of their life cycle. This change moves SE to be directly involved in enterprise strategy and planning, as part of an ongoing and iterative approach to tackling the kinds of societal problems identified in the INCOSE vision.

This evolution of both the role and scope of SE will also see the system of systems aspects of all system contexts increase. We can expect System of Systems Engineering to become part of the systems engineering of many, if not most, SE life cycles.

Evolution of Fundamentals

These ongoing changes to SE place more emphasis on the role of autonomous agents in systems engineering, and agency will be an area of increased emphasis in the systems engineering and SEBoK of the future. Hybertson (2019) spells out in more detail the increased role of agents and agency in future SE. Moving from a total control model to a shared responsibility model changes the nature of engineering to something more like collective actualization, as proposed by Hybertson (2009 and 2019). Systems will represent a combination and interplay of technology and social factors, and they can range from technical product to service provider to social entity. In many cases they will be a socio-technical combination or hybrid.

The above trends have an impact on SE foundations, including technical aspects, social aspects, and ethical aspects. Inclusion of people in systems implies significant expansion of foundation sciences, to provide principles, theories, models, and patterns of the human, biological, social, and agent realm as well as the technical and physical realm. Emphasis on agents implies a revised conceptualization of system change, from the traditional model of mechanistic and controlled fixes and upgrades to a more organic change model that involves growth, self-learning, self-organizing, and self-adapting. Ethical considerations will include how to allocate responsibility for a system in a shared responsibility model. Further discussion of the expanded foundation and a list of foundation disciplines for future SE are presented in (Hybertson 2009 and 2019).

SEBoK Users and Uses

SEBoK Users and Uses

Contents of this Knowledge Area

- Guidance for Systems Engineering Novices
- Guidance for Systems Engineers
- Guidance for Engineers
- Guidance for Systems Engineering Customers
- Guidance for Educators and Researchers
- Guidance for General Managers

-

The SEBoK is intended to be a resource that can help anyone understand more about systems engineering. Systems engineers should obviously benefit, but so can undergraduate engineering students, those new to the SE discipline, or people who work with systems engineers and want to understand more about what to expect from systems engineering activities. This article explores a variety of personas. Once you determine which persona best represents you, read on to get practical advice on how to utilize the SEBoK.

Personas

In marketing, "personas" are used to illustrate potential users or customers. Personas are fictional characters that represent a demographic of a target audience. For the SEBoK, we've developed personas that represent different types of people who we anticipate will utilize the SEBoK:

- An engineering undergraduate student
- A new systems engineer
- An experienced systems engineer
- A chief systems engineer
- An organizational manager
- A systems engineering educator or researcher
- A general manager

Note that initial work on personas was published in (Hutchison et al. 2023). The personas published in this reference were built upon and edited to support this article.

An Undergraduate Engineering Student

Stueti is in her final year studying electrical engineering at a private university. In her capstone, she works on a multi-disciplinary team, including students from the mechanical and software engineering departments as well. As the team comes together, each student starts talking about using the most advanced techniques and technologies available in their part of the project. The discussion devolves into an argument about how to do this in the time and budget available. Her faculty advisor says that in order to be successful, they have to work together to create a useful product, which means that they can't each focus on their own parts in isolation. The advisor suggests that they all need to come to the next team meeting prepared to discuss their project as a system. Stueti Googles "systems" when she gets back to her dorm and stumbles on the SEBoK.

For Stueti, the SEBoK begins to expose her to systems concepts. In particular, Stueti could benefit from reading the articles in Part 2: Foundations of Systems Engineering, particularly The Nature of Systems, which will introduce her to different views on and core definitions of a system. From there, the articles in the Introduction to Systems Engineering knowledge area would be useful. Finally, Stueti reads the article Systems Engineering and Mechanical Engineering, which relates to this new subject area that she has spent several years learning. In her reading, Stueti finds a few references that she thinks will help her better understand this SE stuff and help her apply it.

This gives Stueti a better understanding of what her professor meant – that all the different elements of the project (or system) must work together to achieve their project goal. As the capstone progresses, Stueti returns to the SEBoK to find additional resources as new issues come up.

If you identify with Stueti, review the recommendation for SE novices.

A New Systems Engineer

Hans completed a master's in computer science three years ago and has since been working for a small company in their IT department. The team he is on has been operating and maintaining the existing customer support system, which has become increasingly cumbersome and costly. Han's manager noticed that he was always asking good questions, and several times Hans's curiosity helped the team uncover the root causes of problems. Hans has also exhibited "out of the box" thinking, which has helped create some novel solutions. Hans's computer science and programming skills are competent. The company creating a new customer support system and, based on his experience with the current system and his inquisitiveness, Hans's manager asks if he would consider taking a role as the software systems engineer. In that role, he would be reporting directly to the chief systems engineer on the project. Hans looks forward to new responsibilities, but other than a few brief interactions with systems engineers, he's not sure what they do. He is enrolled in the company's introductory systems engineering course in a few weeks, but he wants to start understanding more about it now.

Han's manager recommends he take a look at the SEBoK in preparation for his upcoming course. Hans, feeling a bit nervous, decides to search the SEBoK for "computer science" and finds the page, Exploring the Relationship between Systems Engineering and Software Engineering. This is a page about a paper by the same title, which Hans looks up to read later. In the SEBoK, he notices that this is used in something called, Software Engineering in the Systems Engineering Life Cycle. Hans reads this article and finds a number of related articles on the relationship between systems engineering and software engineering, which highlight the relationships between the two. Hans is now feeling more confident that this "systems stuff" isn't completely different from what he has learned by applying his computer science degree on the job.

Hans continues to explore the SEBoK, finding a collection of articles about systems thinking, which he finds useful and which leads him to articles about the systems engineering process. He learns about lifecycle approaches and finds an article on agile systems engineering. He is very familiar with agile approaches from his work over the last three years. While reading the SEBoK, Hans looks at the references and identifies 6 articles and 2 books he wants to read to get more familiar with SE. He is feeling much more confident about his ability to tackle the upcoming course and his new role and bookmarks the SEBoK for future reference.

If you identify with Hans, review the recommendations for experienced engineers new to systems engineering.

An Experienced Systems Engineer

Yan has been working in a large company that makes medical devices for the last 10 years, ever since she earned her undergraduate degree in electrical engineering. Within a few years of joining the company, Yan was selected for a "high potential" program to develop new systems talent in the company. As part of the program, Yan completed her graduate degree in systems engineering last year. Currently, she is a lead designer on one of the company's flagship products. She has taken all the courses her company offers around systems design and engineering and is looking for more resources to continue to develop her skills.

Yan is aware of the SEBoK and has read a few articles but has not used it often. She decides to search the SEBoK for "knowledge skills abilities" (KSA) as her company uses this term when evaluating performance. She finds articles on enabling individuals, ethical behavior, and roles and competencies. She reads the roles and competencies articles and learns about several different competency models. Primary references in these articles point her to these models, and she decides that the NASA's Systems Engineering Competencies model seems to align well with how her company views systems engineering. She decides to look through the competency model and see what competencies she has and which she might want to work on. She is generally comfortable with the competencies around the systems engineering lifecycle. She has had a few minor leadership roles, but some of the technical management competencies are less familiar. Yan decides that learning more about technical management will improve her skillset and make her more valuable to the company.

She skims the articles on Technical Management Processes in the SEBoK, and the overview content is pretty familiar. Looking through the works cited and primary references, however, she finds a few really useful references. This leads to the definition of technical management in the SEBoK Glossary of Terms, which points to a joint INCOSE/Project Management Institute (PMI) working group on the subject. Yan reaches out to this group and identifies further resources for self-study. After reviewing these resources, Yan is now more familiar with the vocabulary of technical management and looks for related short courses to help her hone her skills.

If you identify with Yan, review the SEBoK guidance for systems engineers.

A Chief Systems Engineer

Jacquie is a chief systems engineer at a mid-size electronics company. She has led teams to successfully deliver several projects, over the years coordinating hundreds of engineers, project managers, and specialists. Jacquie has recently been asked to step in and support the lead engineers in several smaller projects to resolve some common challenges. She has noted that in almost every case, the issues have two root causes: lack of systems perspective and lack of coordination between teams of different disciplines. Jacquie has seen several initiatives to move the workforce in one direction or another fail over her 18 years with the company, so is wary of top-down mandates saying that everyone needs to become a systems thinker or something similar.

Jacquie is a long-time user of the SEBoK and remembers that there's a section somewhere about enabling systems engineers. She quickly finds the section in the Outline (Part 5: Enabling Systems Engineering) and she notices a knowledge area on Enabling Businesses and Enterprises and starts reading. The articles on determining what capabilities organizations need and developing those capabilities are particularly helpful and lead her to a Harvard Business Review article on change management that is really useful.

Armed with this information, Jacquie gets a group of her peers together to discuss the challenges and some potential solutions.

If you identify with Jacquie, review the recommendations for experienced systems engineers.

An Organizational Manager

The primary audience of the SEBoK is individuals working in the SE discipline, but articles are written in a way that should enable non-systems engineers to grasp the basics.

Juan is a mid-level manager at a large firm that makes major weapons systems for his nation's defense department. The organization is trying to alter the culture toward a more integrative and collaborative model. This includes a focus on systems and systems thinking. Juan's leadership has emphasized that it is critical for all levels of management to show support for this initiative and that, without their support, the initiative cannot be successful. Juan has never heard the term "systems thinking" before and the only connotation he has with "systems" is the company's IT systems that are always causing headaches.

Juan Googles “systems thinking” and is immediately overwhelmed by the search results. Inundated with definitions from companies trying to sell systems thinking services or training, universities advertising their programs, and blog posts, which could be by experts or by people who only think they know what systems thinking is, Juan is quickly overwhelmed. He stumbles upon something that links “systems thinking” to “systems engineering”, which is a term he knows, though he has never been and has no desire to be an “engineer”. He refines his search to include both “systems thinking” and “systems engineering” in Google Scholar to try to find more reputable sources. Again there are tens of thousands of results. He goes to a systems engineer whom he often sees in the break room, and asks him what to do. The systems engineer points him to the SEBoK.

In the SEBoK, Juan quickly finds a knowledge area on systems thinking and several articles and papers that he believes he can trust to give authoritative information. After reading through the articles and references, Juan now feels he has a basic understanding of what systems thinking is and he now understands why this is such a critical part of the company's strategy for change. Juan now has the vocabulary and knowledge to support the initiative as a member of the management team.

If you identify with Juan, review the guidance for general managers.

Guidance for Systems Engineering Novices

-

Some users of the Systems Engineering Body of Knowledge (SEBoK) may be new to the field. This article provides recommended readings for such a user.

Learn the Basic Terms

As discussed in the Introduction to the SEBoK, there are four key terms that you should first understand when learning about systems engineering (SE):

- A system is "a collection of elements and a collection of inter-relationships amongst the elements such that they can be viewed as a bounded whole relative to the elements around them." Open systems exist in an environment described by related systems with which they may interact and conditions to which they may respond. While there are many definitions of the word "system," the SEBoK authors believe that this definition encompasses most of those which are relevant to SE.
- An engineered system is an open system of technical or sociotechnical elements that exhibits emergent properties not exhibited by its individual elements. It is created by and for people; has a purpose with multiple views; satisfies key stakeholders' value propositions; has a life cycle and evolution dynamics; has a boundary and an external environment; and is part of a system-of-interest hierarchy.
- Systems engineering is "an interdisciplinary approach and means to enable the realization of successful (engineered) systems." It focuses on holistically and concurrently understanding stakeholder needs; exploring opportunities; documenting requirements; and synthesizing, verifying, validating, and evolving solutions while considering the complete problem, from system concept exploration through system disposal.
- A systems engineer is "a person who practices systems engineering" as defined above, and whose systems engineering capabilities and experience include sustained practice, specialization, leadership, or authority over SE activities. These activities may be conducted by any competent person regardless of job title or professional affiliation.

Get an Overview

The next step for someone new to SE is get an overview of the discipline. Part 1: SEBoK Introduction contains four articles particularly helpful to one new to SE.

- The article Systems Engineering Overview frames systems engineering inside the larger topic of 'Systems Science.'
- The article Economic Value of Systems Engineering makes the business case for investing in systems engineering as a way to reduce total ownership cost.
- The article Systems Engineering and Other Disciplines discusses briefly how systems engineers and other engineers interact as they develop complex systems together.
- Finally, the article Systems Engineering: Historic and Future Challenges gives a quick history of the discipline and discusses what lies ahead.

Learn About Systems

Engineering is often described as the application of science to develop new products or systems. Part 2: Foundations of Systems Engineering describes some of the underlying systems principles that form the foundation for systems engineering.

- The Knowledge Area on Systems Fundamentals contains five articles. What is a System? is recommended for a new user.
- The Knowledge Area on Systems Science presents two articles on its history and approaches. Both are recommended.
- The Knowledge Area on Systems Thinking has four articles. The first, What is Systems Thinking?, is recommended on a first reading.
- One of the most important current research and practice areas of SE is Model Based Systems Engineering (MBSE). The Knowledge Area Representing Systems with Models provides the foundation for MBSE. The first three of the five articles in the KA are recommended.

Learn How the Systems Approach Is Applied to Engineered Systems

The Knowledge Area Systems Approach Applied to Engineered Systems describes how systems science and systems thinking lead to the practice of systems engineering. All eight articles are recommended.

- Overview of the Systems Approach
- Engineered System Context
- Identifying and Understanding Problems and Opportunities
- Synthesizing Possible Solutions
- Analysis and Selection between Alternative Solutions
- Implementing and Proving a Solution
- Deploying, Using, and Sustaining Systems to Solve Problems
- Stakeholder Needs Definition
- Applying the Systems Approach

Explore the Methods of Systems Engineering

The SEBoK uses a life-cycle framework to describe the processes that comprise systems engineering. Part 3: SE and Management contains the plurality of the content of the SEBoK in eight knowledge areas. A new user should be familiar with the introductions to each of these Knowledge Areas, and should read further in those KAs of interest.

- Life Cycle Models
- System Concept Definition
- System Definition
- System Realization
- System Deployment and Use
- Technical Management Processes
- Product and Service Life Management
- Systems Engineering Standards

Explore the Applications of Systems Engineering

The SEBoK partitions the body of knowledge between methods and areas of application. Areas of application are classified as:

- Product Systems Engineering
- Service Systems Engineering
- Enterprise Systems Engineering
- Systems of Systems (SoS)

A new user should read the introduction to Part 4: Applications of Systems Engineering and to the four knowledge areas listed above. The reader's interests can then suggest which further reading should be done.

Read Case Studies

Finally, the new user should scan the case studies and vignettes in Part 7: SE Implementation Examples and read a few of those in areas that appeal to the reader. This will help reinforce the fundamentals as well as illustrate the practice of SE.

The following case studies are included:

- Successful Business Transformation within a Russian Information Technology Company
- Federal Aviation Administration Next Generation Air Transportation System
- How Lack of Information Sharing Jeopardized the NASA/ESA Cassini/Huygens Mission to Saturn
- Hubble Space Telescope Case Study
- Global Positioning System Case Study
- Medical Radiation Case Study
- FBI Virtual Case File System Case Study
- MSTI Case Study
- Next Generation Medical Infusion Pump Case Study

For Later Reading

Part 6: Related Disciplines contains a broad selection of Knowledge Areas and Topics that describe how systems engineers work with other disciplines. The Knowledge Area on SE and Software Engineering is particularly important, as modern systems get much of their functionality from software.

Part 5: Enabling Systems Engineering has KAs describing how individuals, teams, and organizations can develop to practice effective systems engineering.

A person new to SE should become familiar with several references that are beyond the SEBoK. They include the INCOSE Handbook, several standards (listed in Relevant Standards), and the main journals of systems engineering (including but not limited to *Systems Engineering*, the *Journal of Enterprise Transformation*, and *Systems, Man, and Cybernetics*).

Guidance for Systems Engineers

-

Both for the entry-level systems engineer learning the discipline of systems engineering (SE), and the more experienced systems engineer seeking the knowledge required to accomplish a work activity, the SEBoK serves as a primary information source and a quick, comprehensive reference for SE information.

What these system engineers find in the SEBoK includes:

- definitions of terms,
- explanations of basic concepts and principles,
- useful discussions of topics,
- references to articles and textbooks that cover topics in-depth, and
- pointers to additional sources.

How Systems Engineers Use Topics

Researching SE-related subjects, identifying educational resources, and connecting with individuals or organizations which offer specialized expertise are all part of the job for the practicing systems engineer. The time available to the SE for these activities can be quite limited. The SEBoK is designed to ease the pressure on the systems engineer in this situation, in several ways:

- Because its content is based on research, proven practices, and emerging knowledge, the SEBoK makes high-quality information available to the systems engineer right away.
- Being composed of articles of 2000 words or less in most cases, the SEBoK enables the systems engineer to quickly get an overview of relevant topics.
- By providing primary references, each topic offers a direct route to more detailed information.
- Even greater detail, breadth, and a sense of what's relevant in the SE literature are available through the additional references each topic provides.
- Since the SEBoK sources have been reviewed and vetted by a team of experts, the SEBoK helps the systems engineer avoid less reliable information which can be hard to eliminate within Internet search results.
- The systems engineer who needs to connect with educators and researchers can find relevant names and institutions in SEBoK topics and references.

Systems engineers using the SEBoK may choose one or more of several approaches:

- searching on keywords or article names, using the text field, Search [1] button, and Go [2] button at the top right of each SEBoK page

- scanning the Quick Links, Outline (where the table of contents is located), or Navigation indexes that appear at the left of each SEBoK page, and following links from there to articles that seem likely to be of interest
- searching on keywords using an Internet search engine
- reading through one or more of Parts 1 through 7 in sequence

Reading the SEBoK in sequence is especially suitable for the practicing engineer who is new to SE or is enrolled in an SE-related training course. For this engineer, SE (or some aspect of it) is a subject to be learned comprehensively. This is made easier by navigation links from each article to the previous, next, and parent articles as found in the Table of Contents.

For practicing systems engineers, having the SEBoK makes it possible to gain knowledge more quickly and reliably than they would otherwise. The goal is to spend less time searching for and compiling new information from disparate sources and more time getting work done.

For a team of practicing engineers, the gap in knowledge between more- and less-experienced engineers can be a major obstacle. The SEBoK serves as a tool for the team to build a framework of agreed-upon definitions and perspectives. The consistency of such a framework enhances communication across the team. New teams, especially, can benefit from bridging the gap between legacy and more-recently-acquired knowledge. For more information, see Enabling Teams in Part 5.

How Systems Engineers Use the Examples

The SEBoK is written, for the most part, independent of any particular domain of practice. By design, parts 1 though 6 focus on the discipline of SE and not the numerous domains where SE can be applied.

This lack of domain-specific content is partly offset by Part 7, Systems Engineering Implementation Examples, which consists of case studies and examples drawn from a number of domains where SE is applied. Each example demonstrates the impact of a particular application domain upon SE activities. Examples are generally most useful to the systems engineer when they are aligned with the domain in which the he or she is working, but sometimes ideas from an example in one domain can be usefully applied to situations in another.

Example: Model-Based Systems Engineering Practitioners

For practitioners of model-based systems engineering (MBSE), the Representing Systems with Models knowledge area is of central importance within the SEBoK.

Academic faculty who use the SEBoK to support curriculum development and assessment can refer to the same knowledge area to ensure that their curricula accurately cover the languages and/or methodologies such as System Modeling Language (SysML) and Object-Process Methodology (OPM).

SE researchers, too, can adopt an MBSE approach, making their research products more formal and rigorous by basing them on models.

In MBSE, models of systems support system life cycle activities, including requirements engineering, high-level architecture, detailed design, testing, usage, maintenance, and disposal.

Vignette: Systems Engineering for Medical Devices

Tara Washington has worked as a engineer for the HealthTech medical device company for seven years. Besides continuing to improve her strong software skills, she has shown an aptitude for systems thinking. To better understand the products that her software supports, Tara has taken courses in electrical engineering, mechanical engineering, and physiology. The coursework has helped her to perform effectively as a software system analyst on the SE teams of her last two projects.

HealthTech's Research Division proposes a new concept for a highly programmable radiation therapy device that monitors the effects of the radiation on various parts of the body and adjusts the parameters of the radiation dosage to maximize its effectiveness, subject to a number of safety constraints. The software-intensiveness of the device leads Tara's project manager to recommend her as the lead systems engineer for the design and development of the product.

Tara welcomes the opportunity, knowing that she possesses enough domain knowledge to take the lead SE role. Even so, she realizes that she has picked up SE skills mainly by intuition and needs to build them up more systematically. Tara begins to consult some of HealthTech's lead systems engineers, and to study the SEBoK.

After reading the SEBoK Introduction, Tara feels that she has a solid overview of the SEBoK. Tara finds that the next topic, Scope and Context of the SEBoK, outlines the key activities that she expects to lead, along with others which will require her to collaborate with systems developers and project and systems management personnel.

The same topic identifies those parts of the SEBoK that Tara needs to study in preparation for her lead systems engineer role:

- SE concepts, principles, and modeling approaches in Part 2 (Representing Systems with Models knowledge area (KA))
- life cycle processes, management, technical practices, in Part 3 (Systems Engineering and Management KA)
- approaches for specifying, architecting, verifying and validating the hardware, software, and human factors aspects of the product, as well as common pitfalls to avoid and risks to manage, also in Systems Engineering and Management
- guidelines for the systems engineering of products, in Part 4: Applications of Systems Engineering, including references
- SE knowledge, skills, abilities, and attitudes (KSAAs) needed for a project in Part 5: Enabling Systems Engineering including references
- specialty engineering disciplines that may be key to the project's success, in Part 6: Related Disciplines

Tara's awareness of the deaths caused by the Therac-25 radiation therapy device motivates her to study not only the System Safety topic in Part 6, but all of its key references as well.

While reading about SE life cycle process models in Systems Engineering and Management in Part 3, Tara notes the reference to the Next Generation Medical Infusion Pump Case Study in Part 7. This case study strikes Tara as highly relevant to her medical-device work, and she observes that it is organized into phases similar to those used at HealthTech. From the case study, Tara gains understanding of how a project such as hers would progress: by concurrently evaluating technology opportunities, by discovering the needs of various device stakeholders such as patients, nurses, doctors, hospital administrators, and regulatory agencies, and by working through increasingly detailed prototypes, specifications, designs, plans, business cases, and product safety analyses.

The case study mentions its source: Human-System Integration in the System Development Process [3] (Pew and Mavor 2007), published by the U.S. National Research Council. Tara obtains this book. In it, she finds numerous good practices for human-systems needs analysis, organizational analysis, operations analysis, prototyping, usability criteria formulation, hardware-software-human factors integration, process decision milestone review criteria, and risk management.

As a result of her SEBoK-based study, Tara feels better-qualified to plan, staff, organize, control, and direct the SE portion of the HealthTech radiation therapy device project and to help bring the project to a successful conclusion.

How Systems Engineers Use the Emerging Knowledge

The SE discipline continues to mature and evolve, incorporating new ideas, processes, and technologies. The SEBoK part on Emerging Knowledge describes some of these trends. For example, it currently includes references to the incorporation of artificial intelligence (AI) to support systems engineering.

Summary

In the SEBoK, practicing engineers have an authoritative knowledge resource that can be accessed quickly to gain essential high-level information, and to identify the best references for in-depth study and research into SE topics when an individual's initial level of understanding is not adequate to get the job done.

The SEBoK is also a resource for practicing engineers who teach, as well as those taking training courses.

Guidance for Engineers

-

The realization of successful complex systems requires experts from many disciplines to work together. This makes the SEBoK useful to engineers with backgrounds in biomedical, civil, electrical, chemical, civil, materials, mechanical, software, and many other engineering disciplines.

Studying the SEBoK enables engineers from disciplines other than systems engineering (SE) to:

- see why good systems engineering practice must involve multiple disciplines,
- appreciate a broader view of systems beyond their specialties,
- understand how their contributions fit into the larger systems picture, and
- prepare to solve more difficult and encompassing problems.

In many cases, engineers who study systems engineering as a supplement to their area of specialization find their professional value enhanced when they put the new knowledge into practice.

Use of Topics

For engineers from non-SE backgrounds, each part of the SEBoK contributes something to the experience of learning about systems engineering.

- Part 1: SEBoK Introduction provides an overview both of systems engineering and of the SEBoK itself
- Part 2: Foundations of Systems Engineering highlights the areas of systems knowledge most relevant to systems engineering, providing a foundation for the theory and practice of systems engineering as explained in Parts 3, 4 and 5
- Part 3: Systems Engineering and Management includes the knowledge areas of Life Cycle Models, System Definition, System Realization, and System Deployment and Use, all highly important when approaching the study of SE from another discipline
  - Also in Part 3, Technical Management Processes includes such relevant topics as risk management, measurement, configuration management, and quality management
- Part 4: Applications of Systems Engineering identifies the SE activities for four kinds of engineered systems, namely products, services, enterprises, and systems of systems (SoS)
  - The primary references and glossary terms — not just the content — for a given type of system are essential reading for an engineer developing or modifying a system of that kind
- Part 5: Enabling Systems Engineering, especially Team Capability, explains how systems engineers and other types of engineers fit into the larger picture of enabling individuals and teams to perform systems engineering activities, and into the larger picture of systems engineering organizational strategies
- Part 6: Systems Engineering and Other Disciplines is key for engineers from non-SE backgrounds
  - Within Part 6, Systems Engineering and Project Management should be of interest to almost all readers, while Systems Engineering and Software Engineering and Systems Engineering and Quality Attributes are naturally most essential for engineers in the respective disciplines
- Part 7: Systems Engineering Implementation Examples illustrates how systems engineering practices, principles, and concepts are applied in real settings and contain universally useful insights

Engineers may be tempted to skip over knowledge areas or topics that sound more like management than engineering stories, for example Technical Management Processes in Part 3 or Part 5. This temptation should be resisted, because these topics are actually about how SE orchestrates the efforts of multiple disciplines, not management in the administrative sense.

Finally, the extensive lists of references throughout the SEBoK provide a basis for further readings.

Vignette: Software Engineer

José Wilks is an entrepreneurial software engineer who wants to learn more about systems engineering principles applied to embedded systems for advanced document identification and verification. He wants to implement best practices in developing highly secure systems for real-time image processing and forensic verification of documents. His company provides a rapid, secure and cost-effective solution for verifying the authenticity of identification, travel, and financial documents, with technology that runs on proprietary tablet computers for portable and fixed locations.

José is knowledgeable about computer hardware engineering, low-level interfaces between hardware and software, and the related tradeoffs in embedded devices. His company has developed research prototypes, but without the stringent security requirements for actual field usage linked to government identification databases. The few experimental units which have been sold have fared well in limited testing, but José wants to expand into markets for government agencies, law enforcement departments and the private sector. To make headway into those diverse markets, he will need to confront abundant new constraints and challenges.

José begins his study of SE by skimming the SEBoK Introduction and the Scope and Context of the SEBoK to get an overview of the SEBoK contents. As he reads, he sometimes refers to the *Software Engineering Body of Knowledge (SWEBoK)* (Bourque and Fairley 2014), which José already knows from his many years of experience on software projects. In the SEBoK, José is looking for nuggets of knowledge and pointers that can help his enterprise expand. Here are his notes:

- Part 3: Systems Engineering and Management has concepts that are new to us and that may work. Extra system-level verification and validation (V&V) gates identified in Life Cycle Models can be incorporated in company processes, and the references can help with implementation details. There is also material about system-wide procedures beyond software V&V, and about where to find testing and regulation standards used by various government entities. Together with the traditional software testing already in place, these processes could ensure conformity to the regulations and expedite the product's approval for use.
- Though the system concept is proven, the company must still convince potential buyers of the system's financial benefits while demonstrating that all security criteria are satisfied. To do that, we must better understand the needs of the stakeholders. In expressing system requirements and benefits, we need to start using the terminology of users, corporate/government purchasers, and regulatory agencies. Stakeholder Needs Definition is relevant here. The company needs to quantify expected return on investment (ROI) for its products.
- System Realization addresses our broader V&V concerns. We need to demonstrate the measures we are taking to boost reliability of system performance. The standard models and measures for system reliability described in the SEBoK are new to us — now staff must develop tests to quantify important attributes. We may want to model reliability and system adherence to regulations using a form of model-based systems engineering (MBSE). We can learn more about this from the references.
- Technical Management Processes makes it clear that new configuration management (CM) and information management (IM) procedures need to be adopted for federal database controls and integrity. We can use the references in Systems Engineering Standards to learn how to define processes and develop test cases.
- Part 5: Enabling Systems Engineering makes a convincing case that having the right people for a new systems engineering culture is critical. We should probably hire a systems engineer or two to augment our engineering department expertise.
- Our application must deal with private data concerns, and Part 7: Systems Engineering Implementation Examples, particularly the FBI Virtual Case File System Case Study, could help us avoid pitfalls that have hurt others in similar situations. We can put this in context based on Security Engineering in Part 6: Related Disciplines, and then follow up with further study based on the references.

Now José feels that he is better prepared to adapt his processes for new system lifecycles and environments, and that he can see a clear path through the morass of agencies and regulations. His priorities are to quantify the value

proposition for his technology innovations, make inroads into new markets, and strengthen his staff for the long-term enterprise.

Vignette: Mechanical Engineer

Cindy Glass is a mechanical engineer whose experience in the petroleum industry has focused on large-scale oil extraction equipment in the field. Now Cindy is tasked with helping to manage the development of new offshore oil platforms featuring robotic technology and computer networks. This calls for incorporating SE principles from day one to cope with the systems considerations, which are broader than anything in Cindy's previous experience.

Some of the drilling is to be done with remote-controlled, unmanned underwater vehicles (UUVs). Along with safety, which was always a major concern, cybersecurity now takes center stage. Hostile state actors, “hacktivists,” or others could cause havoc if they succeed in taking control of the remote vehicles or other infrastructure. Unfortunately, software system implementation is completely new to Cindy, who realizes that this entails dealing with many more engineering disciplines and dimensions of system constraints than she previously encountered.

Cindy is accustomed to implementing minor design changes in existing equipment, with automation and safety guidelines already in place. Now she is starting from scratch with the earliest stages of the platform lifecycle. While Cindy understands tradeoffs involving mechanical sub-systems like rigs and drilling materials, she must now broaden her system analysis to include new environmental constraints and system security.

Cindy consults the SEBoK and discovers that for her effort to understand system design with many "-ilities," System Realization is a good starting point and its references should provide the in-depth information she needs.

The project lifecycle requires pursuing several major activities concurrently:

- engineering platform sub-components
- evaluating technology opportunities
- understanding the needs of all stakeholders inside and outside the company
- progressing through increasingly detailed prototypes, working slices of software, system specifications, designs, plans, business cases, and security and safety analyses of the platform architecture and its operations.

To understand how to manage such a project lifecycle, Cindy turns to Part 3: Systems Engineering and Management. The planning section provides detailed advice for starting out. Cindy expects to conduct her management activities on a rigorous basis, to consider the interfaces between the engineering specialties, and to produce a project plan that calls for a broad set of integrated management and technical plans.

Being new to the software development world, Cindy reads The Nature of Software and Key Points a Systems Engineer Needs to Know about Software Engineering, and consults the SWEBoK [1] for references on software engineering.

These readings show Cindy how closely systems engineering and software engineering are intertwined. For example, they remind her to include security specialists at both the software level and the systems level from the beginning.

From her initial plunge into study of the SEBoK, Cindy has gained an appreciation of the wide range of system constraints for which she must account, and the many engineering disciplines she must work with as a result. She plans to consult the references in the SEBoK on each unfamiliar subject that she encounters throughout the architecting, design, development and deployment of the new platforms.

Summary

Engineers from disciplines other than systems engineering benefit from the insights about SE principles that the SEBoK provides. Studying the knowledge areas highlighted in this use case and the sources to which their references point can help such engineers become more interdisciplinary. Ultimately, they can consider broadening their work responsibilities, rendering them more valuable to their employers and society.

Guidance for Systems Engineering Customers

-

Customers of systems engineering (SE) provide resources to SE organizations and individuals, and receive SE products and services in return. They are among the stakeholders for a system-of-interest (SoI). They and other stakeholders express needs and expectations for results that systems engineers provide.

Although their main SE activity is helping to define the system, customers must take account of all life cycle aspects. The better they understand the activities that systems engineers perform, the better customers know what to request, how to request it, how much to pay for it, and how to judge the quality and value of the results of systems engineering. In short, what customers need to grasp is how systems engineers participate in the realization of engineered systems resulting in products, services, enterprises, and systems of systems (SoS).

The SEBoK assists the customers of systems engineering by providing a broad, comprehensive treatment of the concepts, principles, theory, and practice related to systems in general and SE in particular. Its references inform customers about books and articles that provide important perspectives on systems and SE.

Customers of SE include:

- sponsors of internal SE organizations,
- organizations that maintain long-term customer-domain relationships with external SE organizations, and
- organizations that outsource SE functions to general-purpose SE organizations.

The two vignettes below show how the SEBoK can assist SE customers. In one, the customer of an internal, corporate SE organization leads the transition to a mobile supply chain management system. In the other, the customer of a mixture of customer-domain and other SE organizations presides over the SE of a catastrophe-response SoS, which entails integration over multiple domains.

Use of Topics

For customers of SE, most parts of the SEBoK offer immediately relevant knowledge about SE.

Part 1: SEBoK Introduction:

- explains the relationship between SE, system development, and project management,
- summarizes overall trends in the rate of growth of systems interdependency, complexity, assurance levels, and pace of change, and of the evolving nature of integrated hardware-software-human systems, and
- provides pointers to other parts of the SEBoK of interest to customers.

Part 3: Systems Engineering and Management:

- explains evolving system life cycle models and their elements, indicating which elements are SE-intensive (see Life Cycle Models),
- provides overall perspectives on customer participation in SE activity,
- identifies customer influence points on SE activity, and
- explains how customers can express their concerns in the form of needs, expectations, and requirements.

Part 4: Applications of Systems Engineering:

- explains how the SE function varies by class of system product, service, enterprise, and systems of systems engineering).

Part 6: Systems Engineering and Other Disciplines:

- explains how SE relates to project management, procurement and acquisition, and specialty engineering for such customer-intensive specialties as safety, security, maintainability, usability, and affordability.

Part 7: Systems Engineering Implementation Examples:

- provides case studies and examples to illustrate how the parts have been used in similar situations, presenting successes to emulate and failures to avoid.

If there is a central theme here, it is that the quality of customer input is critical. That is because the systems engineer evaluates customer input, then uses it in formulating an approach to defining and realizing the system. Part 3 addresses this, explaining that the customer should expect the systems engineer to provide:

- a well-architected product, service, enterprise, or system of systems that meets customer needs and expectations (again, this depends on high quality input from stakeholders — see System Definition)
- a managed life cycle model from the customer need and requirements to the delivered product, service, enterprise or system of systems (see Life Cycle Models)
- both verification that the system-of-interest (SoI) meets the needs and requirements of the stakeholders, and validation that the final result, when deployed in an operational environment, provides the value added that was desired are critical to systems engineering (see System Realization and System Deployment and Use).

Implementation Examples

Good examples provide a basis for deeper understanding. In Part 7, the SEBoK provides summaries of and references to full case studies and examples. These are linked back to the appropriate areas of the SEBoK and a matrix is provided that shows the primary areas of the SEBoK addressed by each example. Readers can use the matrix to find case studies and examples- and through these, references - that relate to their concerns.

Vignette: Mobile Supply Chain Management

Barbara Bradley is the Director of Supply Chain Management Systems for a large manufacturing company. Her main area of expertise is transportation logistics. She has led the evolution of a highly successful corporate supply chain management system based on desktop and mainframe technology, more by making incremental strategic choices than by applying formal SE.

Now, many of her suppliers and distributors adopt mobile devices and cloud services and Barbara sees that her own company must do the same. The company's status quo approach of incremental, ad hoc choices is clearly inadequate for a technology transition of this magnitude. Not only that, but the company must evolve to the new mode of operation while providing continuity of service to the supply chain stakeholders.

Barbara decides that these challenges require formal SE. As a first step, she plans to put together a Next-Generation Supply Chain Management System integrated product team (IPT). Members of the IPT will include Barbara's supply chain experts, her supply-chain success-critical stakeholders, and the corporate SE organization.

Barbara has never used the corporate SE organization before and wants to better understand an SE organization's overall capabilities and modes of operation. She turns to the SEBoK for answers to the questions about SE that are on her mind:

- How do we maintain continuity of service while pursuing incremental development?
  - What choices about life cycle models can make this possible?
- What is the role of the customer in defining systems of interest (SoIs)?
  - How do we provide guidance to the customer in expressing needs, concerns, and requirements?
- What is the role of the customer at early decision milestones?
  - How do we ensure that results of our interaction with the customer include well-architected products and thorough development plans, budgets, and schedules?
- What is the role of the customer in product acceptance, specifically when we verify stakeholder requirements and when we validate the final result?

Barbara seeks the answer to one question in Part 4: Applications of Systems Engineering:

- Given that a supply chain management system combines product, service, enterprise, and SoS views, how do we understand what goes into all those views, and keep the overall picture clear?

Barbara's final question is addressed in Part 6: Systems Engineering and Other Disciplines:

- How do we integrate SE and software engineering (SwE)?

Once in command of the answers to these questions, Barbara is ready to lead the IPT in analyzing, negotiating, and defining an approach that is satisfactory to all of the success-critical stakeholders. By having the IPT members read the portions of the SEBoK that she has found most valuable, Barbara begins to build a shared vision within the IPT. As the IPT defines a Next-Generation Supply Chain Management System and prepares the transition from the old system to the new, the SEBoK is an important tool and resource.

Vignette: Catastrophe-Response System of Systems

Ahmed Malik is the Information Systems Division General Manager in his country's Department of Natural Resources. The country suffers frequent wildfires that destroy crops, forests, villages, and parts of cities, and also cause problems with emergency care, crime prevention, and the water supply.

During a recent catastrophic wildfire, personnel responsible for firefighting, crime prevention, traffic control, water supply maintenance, emergency care facilities, and other key capabilities found themselves unable to communicate with each other. As a result, the Minister for Natural Resources has been tasked with improving the country's catastrophe response capabilities, and has named Ahmed as the SE customer lead for this effort.

The Minister suggests that Ahmed organize a workshop to scope the problem and explore candidate solutions to the communications problems. Ahmed invites the various actors involved in catastrophe response — medical, insurance, and news media organizations from both public and private sectors. He also invites SE organizations with SoS experience.

Ahmed has strong experience in information SE, but none in the development of SoSs. To come up to speed in his role as the SE customer lead, Ahmed turns to the SEBoK Part 3: Systems Engineering and Management. To better

understand the challenges of SoS SE, he studies the SoS knowledge area in Part 4, and its references. Ahmed also schedules meetings with the leading SoS SE provider organizations, who are eager to tell him about their capabilities. Overall, Ahmed looks for both guidance and pointers to candidate solution sources in the SEBoK.

Thus prepared, Ahmed structures the workshop to address three key challenges:

- mutual understanding of organization roles, responsibilities, and authority
- summary analyses of previous catastrophe response communication gaps and needs
- candidate solution capabilities in communications, data access, geolocation services, public emergency warning systems, coordinating evacuation procedures, architectural connector approaches for improving interoperability, and sharable models for evaluating alternative solution approaches.

The workshop brings the primary organizations involved in catastrophe responses together with the most capable SoS SE provider organizations. The results of their discussions provide Ahmed and his Minister with sufficient information to prepare a phased plan, budget, and schedule for incremental development of improved catastrophe response capabilities, beginning with simple interoperability aids and analyses of architecture alternatives for performance, scalability, and feasibility of evolution from the initial simple fixes. The plan is then iterated with the key stakeholders and converged to a common-consensus approach for achieving strong, credible early improvements and a way forward to a much more scalable and cost-effective catastrophe-response SoS.

This vignette is based on the Regional Area Crisis Response SoS (RACRS) in (Lane and Bohn 2010).

Summary

For the customers of SE, the SEBoK provides both general and specific knowledge that will help users gain important insight in relating to systems engineers. Key to this is learning about life cycles, the definition of SoIs, and how to provide guidance in expressing needs, concerns, and requirements. Further, customers need to know what to expect as a result of SE activities in the form of well-architected products, services, enterprises, or systems of systems and a managed life cycle. The results of verification of stakeholder requirements and the validation of the final result in respect to fulfilling the user needs are vital.

Guidance for Educators and Researchers

-

For educators or researchers, the SEBoK should be used together with GRCSE (*Graduate Reference Curriculum for System Engineering*). The SEBoK is a guide to the knowledge that constitutes the systems engineering domain, while GRCSE [1] "describes a program for a professional master's degree focused on developing student ability to perform systems engineering tasks and roles" (Pyster et al. 2012).

An educator, for purposes of this use case, is a university faculty member or a professional trainer. Educators use the SEBoK and the GRCSE to develop curricula or courses focused on systems engineering (SE) generally, on domain-centric systems engineering, or on another engineering discipline that touches on SE. The SEBoK and GRCSE are means to assure accuracy, completeness, and effective assessment at all levels, from lessons through objectives.

A researcher, for purposes of this use case, is a person actively contributing to the body of SE knowledge.

The Use of Topics

Educators can use SEBOK topics and their primary and additional references as:

- assigned readings for courses,
- supplemental references for student research, and
- content for curriculum development.

Educators can also use the concepts, perspectives, and references to develop or refine course objectives and the techniques for assessing them.

Researchers can use SEBoK topics and their primary and additional references to learn about the state of the art in the subject areas of interest, for summaries of the literature, and to look for opportunities to advance those areas by further research.

A good course or research topic should reflect multiple perspectives, which the SEBoK provides. As well, cataloging the wide diversity in accepted practices across SE is an important function of the SEBoK from the researcher's perspective.

For both educators and researchers, the fact that the SEBoK provides both primary and additional references in each topic is useful. So is the fact that the SEBoK is a wiki, which allows frequent updates to keep pace with the dynamic evolution of the systems engineering domain. See Acknowledgements and Release History.

Implementation Examples

Good examples make for good teaching. The Systems Engineering Implementation Examples in the SEBoK consist of relatively in-depth case studies and shorter examples, which are linked back to appropriate areas of the SEBoK. A matrix shows which SEBoK topics are addressed by each case study or vignette.

Each case study in the SEBoK is actually a summary of an original case found in the SE literature, and is accompanied by a reference to the full, published case study. Case study summaries or examples from the SEBoK may be incorporated in curricula.

Educator

University faculty may use the SEBoK and GRCSE to develop:

- a complete SE curriculum,
- a single course in systems engineering, either for use in an SE curriculum, or in a curriculum that belongs to some other discipline, or
- assessment criteria for curricula or courses.

Likewise, professional trainers use the SEBoK to develop training material, or to evaluate or update existing training courses.

Both faculty and trainers pursue professional development, in the form of SE study, using the SEBoK.

Vignette: Curriculum and Course Development

A university designates a faculty team to investigate the feasibility of developing a graduate degree in SE.

Results of preliminary feasibility analysis (including evaluating the market, competing degree programs, and so on) are encouraging. The faculty team then begins to design the program, by identifying:

- program constituents
- potential objectives, outcomes and entrance requirements, based on review of GRCSE
- one half of the curriculum content based on review of the typical curriculum architecture (GRCSE chapter 5) and the core body of knowledge (CorBoK) (chapter 6) of GRCSE and
- the other half of the curriculum content based on review of the SEBoK (Parts 2 through 7) .

According to the GRCSE, 50% of the total knowledge conveyed in a graduate program should be based on the CorBoK, to ensure a common foundation among programs offered at different institutions. At the same time, restricting the CorBoK to no more than 50% encourages a healthy variety in those programs.

Once these steps are complete, the overall architecture and the content and scope of the curriculum are defined. Now the faculty designs the courses themselves, defining in turn:

- the prerequisites for each course
- the overall course sequencing for the curriculum, based on the course prerequisites
- the objectives and goals for each course and
- the expected outcomes of each course.

Finally, the faculty is ready to develop the content for each individual course.

Defining course content is done based on topics in the SEBoK that cover the subject of the course.

Using primary and additional references as much as the topics themselves, the faculty responsible for course design define:

- the scope of the course content
- the course coverage, that is, what within the course content scope is actually taught in the course.

Given the scope and coverage, the next and final step is to develop the course material.

A professional trainer designing the training material performs the same kinds of activities. To customize the training course for a specific industry or customer, the trainer may integrate domain-specific content as well.

Researcher

Researchers use SEBoK topics and their primary and additional references to learn about the state of the art in the subject areas of topics, and to look for opportunities to advance those areas by further research.

Vignette: Software Engineering Research

William McGregor, a software engineer, wants to learn more about software intensive systems (SIS). Initially, William wants to answer the question: Do the activities and practices used to develop SIS represent special treatments of standard activities and practices?

William has already reviewed the SWEBoK and its primary references extensively for an answer to his question. In the course of his research, William learns about the SEBoK and decides to look there, too.

William finds no specific discussion of the SIS within the SEBoK. As he looks through the SEBoK, though, he realizes that there are activities throughout the system development life cycle which can be adapted or customized for the development of SIS. Accordingly, William decides to replace his original question with two new ones: (a) what best practices are applied throughout the software development life cycle and (b) how can those practices be adapted to SIS?

William now focuses on Part 3 to learn about the system development life cycle and identify development activities and practices that he can customize for software intensive systems.

Summary

Educators use the SEBoK as a framework or a resource which helps them:

- determine what subject matter should be included in a new curriculum
- identify gaps in an existing curriculum and craft plans to address those gaps, and
- design individual courses.

The case studies and vignettes in the SEBoK may be used by educators in the classroom.

To develop curricula at the program level, educators should use the SEBoK in tandem with the GRCSE.

Researchers use the SEBoK to learn about the state of the systems engineering discipline, and to look for opportunities to advance that state by further research.

Guidance for General Managers

-

General managers preside over system development projects, system acquisitions, product lines, systems of systems (SoSs), and commercial and government organizations. For general managers, the SEBoK serves as a primary information source and quick, comprehensive reference for systems engineering information.

In particular, the SEBoK helps the general manager understand:

- the boundaries and synergies among systems engineering (SE), systems development, project management (PM), and life cycle support
- how those boundaries and synergies are likely to evolve with increasing use of evolutionary development, lean and agile methods, and systems that provide purchased services as opposed to salable products
- how to best balance a mix of hardware, software, human factors, domain, and specialty-area systems engineers and
- how an organization can evolve to take advantage of the trend towards cross-discipline systems engineers.

Use of Topics

For general managers, most parts of the SEBoK offer immediately relevant knowledge about SE.

Part 1:

- explains the relationship between SE, system development, and project management
- summarizes overall trends in the nature of systems interdependency, complexity, assurance levels, and pace of change
- describes the evolving nature of integrated hardware-software-human systems and
- provides pointers to other parts of the SEBoK of interest to general managers.

Part 3:

- explains evolving system life cycle models and their elements, indicating which elements are SE-intensive (see Life Cycle Models) and
- provides overall guidance on the management of SE activity.

Part 4:

- explains how the SE function varies by class of system product, service, enterprise, and systems of systems engineering).

Part 5:

- explains SE governance and competence development.

Part 6:

- explains how SE relates to software engineering, project management, industrial engineering, procurement and acquisition, and specialty engineering for such specialties as safety, security, maintainability, and usability.

Part 7:

- provides case studies and vignettes to illustrate how the parts have been used in similar situations in successes to emulate and failures to avoid.

Vignette: Emerging Nation Satellite System

Tom Lee is General Manager for Telecommunications in a ministry of a large emerging nation. The government does not have much existing capability for developing capital-intensive infrastructure projects. The government decides to use a major investment in technology as a vehicle to develop national enterprise capabilities.

To accomplish this, the minister assigns Tom to lead a project to develop a national satellite system for telecommunications and earth resources observation. Tom understands that this is a very complex system and decides to do some background research. During this research, Tom discovers the SEBoK and decides that is may be a useful resource.

Tom first reads:

- Part 1 for an overview and pointers to relevant sections of Parts 3 through 6,
- portions of Part 3, Part 4, Part 5, and Part 6 to learn about the life cycle, nature, scope, and management aspects of enterprise SE,
- the successful satellite system case studies in Part 7 (Global Positioning System, Miniature Seeker Technology Integration spacecraft) for approaches to emulate, and
- the satellite system case study in Part 7 which describes development and integration problems (Hubble Space Telescope) for pitfalls to avoid.

Tom continues by carefully reading Part 5. He realizes that he must simultaneously develop individuals, teams, and the enterprise. The knowledge areas (KAs) from Part 5 give useful background. For this project, Tom enlists both a proven multi-national satellite SE company and some of his brightest aerospace systems engineers. Tom expects his local systems engineers to learn from the SE company, and he plans to use them as the core group of the national satellite system as it ultimately develops and operates.

He realizes that correct problem definition and requirements setting will be critical first steps. He carefully reads the System Concept Definition KA. As his team develops the stakeholder needs and the system requirements, he makes sure they follow good practices as listed in the SEBoK. Once architectural designs have been proposed and approved, he requires his team to perform cost-benefit tradeoff analyses of alternative solutions.

Thus prepared, Tom is confident that he can formulate and execute a successful approach.

Vignette: Commercial Safety Equipment Company

Maria Moreno is General Manager at Safety First Equipment Company, specialists in hardware-intensive safety equipment. Maria's background is in electromechanical systems. Safety First is highly successful but beginning to lose market share to competitors who offer software-intensive capabilities and user amenities.

Maria is preparing an initiative to make Safety First into a leading software-intensive safety equipment provider. She decides to make the SEBoK a primary resource for gathering concepts and insights for the initiative. She begins by skimming through all of Parts 1 through 6, both to become familiar with the SEBoK itself and to start organizing her thoughts on SE.

Now Maria is ready to focus on subjects of prime importance to her task. Here are those subjects, listed with the places in the SEBoK where she finds information about them.

In Systems Engineering and Software Engineering in Part 6:

- the nature of software,
- differences between hardware and software architectures and practices and
- key aspects of managing software teams.

In the article Human Systems Integration in the Systems Engineering and Quality Attributes knowledge area, also in Part 6:

- the SE of user amenities.

In the Next Generation Medical Infusion Pump Case Study in Part 7:

- the software aspects of safety practices, such as software fault tree analysis and failure modes and effects analysis and
- overall approaches for concurrent engineering of the hardware, software, and human factors aspects of safety-critical equipment.

In the Medical Radiation Case Study in Part 7:

- hardware-software pitfalls to avoid in safety-critical equipment.

Maria chose the last two items from among the case studies in Part 7 because being safety-critical, they contain lessons directly applicable to her initiative at Safety First.

With this framework of concepts and practical information in place, Maria begins assembling a core team of Safety First systems engineers, complemented by external experts in software and human factors engineering. Maria wants the team to begin by developing a shared vision. To that end, she asks them to read the portions of the SEBoK that she has found most valuable in assessing the challenges of transitioning Safety First into a leading software-intensive, user-friendly safety equipment provider.

Summary

For the general manager whose organization includes systems engineers, the relationship between SE, systems development, project management, and life cycle support is a central concern. The SEBoK provides insights and guidance about this and other aspects of SE principle and practice, and explains the role of SE in a variety of management challenge areas and application domains.

The SEBoK complements the general management guidance available in sources such as the *PMBOK® Guide* (PMI 2013).

Part 2: Foundations of Systems Engineering

Foundations of Systems Engineering

Contents of this Part

- Systems Engineering Fundamentals (Rick Adcock) (Janet Singer, Duane Hybertson, and Gary Smith)
- The Nature of Systems (Randall Anway, Paul McGoey, Curt McNamara, and Gary Smith)
- Systems Science (Rick Adcock) (Gary Smith)
- Systems Thinking (Rick Adcock)
- Representing Systems with Models (Sanford Friedenthal) (Dov Dori and Yaniv Mordecai)
- Systems Approach Applied to Engineered Systems (Rick Adcock) (Janet Singer and Duane Hybertson)

- Lead Author:
- Rick Adcock

- Contributing Authors:
- Scott Jackson, Janet Singer, Duane Hybertson, and Gary Smith

-

Part 2 of the SEBoK provides the conceptual foundations of systems engineering. It equips systems engineers with an understanding of the principles, theories, and practices that underpin their discipline, while also connecting them to the broader traditions of systems science and systems practice. By presenting this wider integrative context, Part 2 makes systems knowledge more accessible both within engineering and to a wider community of practitioners and researchers working across diverse domains.

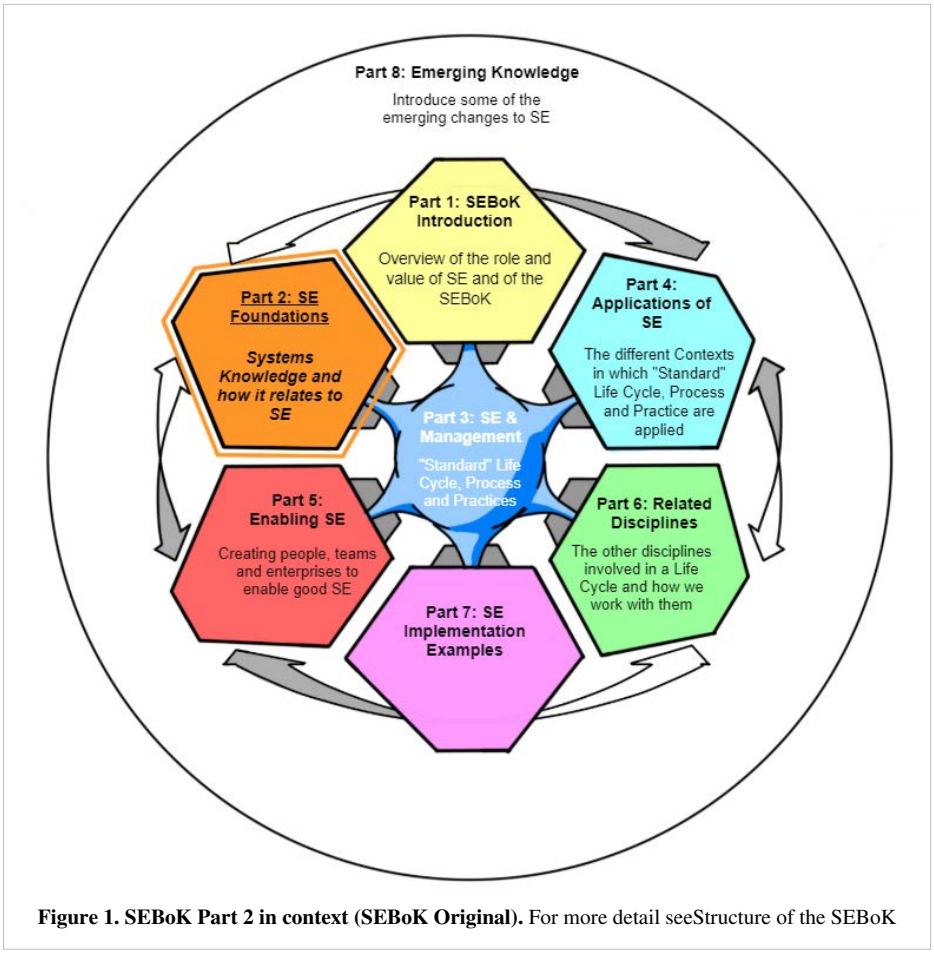

Figure 1. SEBoK Part 2 in context (SEBoK Original). For more detail seeStructure of the SEBoK

This knowledge is included in the SEBoK firstly to help systems engineers benefit from an understanding of the foundations of their discipline, and to provide them with access to some of the theories and practices of systems science and other fields of systems practice. Including this wider integrative systems science context in the SEBoK should also help to make SE knowledge more accessible to a wider audience outside of its traditional domains.

Knowledge Areas in Part 2

Each part of the SEBoK is divided into knowledge areas (KAs), which are groupings of information with a related theme. Part 2 contains the following KAs:

- Systems Fundamentals introduces essential definitions, concepts, principles, and heuristics that underpin all of SE.
- The Nature of Systems explores the diversity of systems in the world, from natural and engineered to socio-technical, and the universal patterns they share.
- Systems Science surveys theoretical advances and enduring insights that support systemic understanding across domains.
- Systems Thinking describes the perspectives, principles, and heuristics that guide how we frame and approach complex problems.
- Representing Systems with Models highlights the role of abstraction and modeling in understanding, designing, and managing systems.
- Systems Approach Applied to Engineered Systems presents structured methods for applying systems concepts directly to real-world engineering practice

Introduction

Most systems engineers are practitioners, applying processes and methods that have been developed and evolved over decades. SE is a pragmatic approach, inherently interdisciplinary, yet specialized in its focus on integration and whole-system effectiveness. Practitioners typically work within a specific domain, using approaches tailored to that domain's problems, constraints, risks, and opportunities. These approaches capture the accumulated knowledge of domain experts regarding the most effective ways to apply systems engineering.

Specific domains in which systems approaches are used and adapted include:

- Technology products, integrating multiple engineering disciplines
- Information-rich systems, such as command and control, air traffic management, or health informatics.
- Platforms, e.g. aircraft, civil airliners, cars, trains, etc.
- Organizational and enterprise systems, which may be focused on delivering service or capability
- Civil engineering/infrastructure systems, e.g. roads networks, bridges, builds, communications networks, etc.

Each domain involves different kinds of systems and requires different skill sets. Yet across this diversity, there are underlying **unifying systems principles** that can enhance the effectiveness of systems approaches in any domain. In particular, shared knowledge of systems principles and terminology improves communication and enables systems engineers to integrate complex systems that span traditional domain boundaries (Sillitto 2012). This integrated approach is increasingly needed to solve today's complex system challenges, but as these different communities come together, they may find that assumptions underpinning their worldviews are not shared.

General Systems Engineering Foundations

To bridge the gap between different domains and communities of practice, it is essential to establish the intellectual foundations of systems engineering and a common language for describing its key concepts and paradigms. An integrated systems approach to complex problems must combine elements of systems theories with practical methods. This ranges from the technical-systems focus that has traditionally dominated engineering to the learning-systems focus used in social and organizational interventions. A shared framework and terminology allow communities with diverse worldviews and skills to collaborate effectively toward common goals.

The SEBoK provides principles and concepts that can support all potential applications of systems engineering, while remaining adaptable to particular contexts. Much of the published knowledge in systems engineering originates from specific domains, such as defense, transportation, health, or enterprise systems, or from particular business models and technology areas. In the SEBoK, this specialized knowledge is generalized where possible, so that it can be applied across related applications.

Generalized knowledge may take different forms. In many cases, it is informal generalization, representing current best understanding across domains or capturing common practices. In other cases, it is based on stronger theoretical considerations, offering explanatory power and predictive value across all special cases. SEBoK typically presents the informally generalized view, while identifying and linking specific knowledge to its broader foundations.

Looking ahead, the *INCOSE Vision 2035* highlights the aspiration for systems engineering to mature into a discipline with a formally defined theoretical basis. Such a theory, once developed, would largely reside within Part 2 of the SEBoK. At present, Part 2 provides generalized foundations with pragmatic value to describe and improve current practice, and it will evolve to incorporate any emerging general theory of systems engineering as it becomes available.

The Systems Praxis Framework

The term systems praxis refers to the combined intellectual and practical effort to create holistic solutions to today's complex challenges. *Praxis* means "translating an idea into action" (WordNet 2012), and in this context highlights the need to integrate appropriate theory with effective practice drawn from many different sources. Because complex challenges cut across disciplinary and organizational boundaries, systems praxis requires diverse communities to work together. To collaborate, they must first establish communication; and to communicate, they must first find shared points of connection.

To support this, members of the International Council on Systems Engineering (INCOSE) and the International Society for the Systems Sciences (ISSS), working through the International Federation for Systems Research (IFSR), developed the *Systems Praxis Framework* (IFSR 2012). This framework represents a first step toward a common language for systems praxis, and it has been adopted in the SEBoK as a way of organizing foundational knowledge. It helps make the concepts and principles of systems thinking and practice more accessible to anyone applying a systems approach to engineered system problems.

The Systems Praxis Framework highlights the flows and interconnections among elements of a broader *knowledge ecosystem* of systems theory and practice. This ecosystem situates systems engineering within an integrative context that links foundations, theories, representations, and approaches to practice.

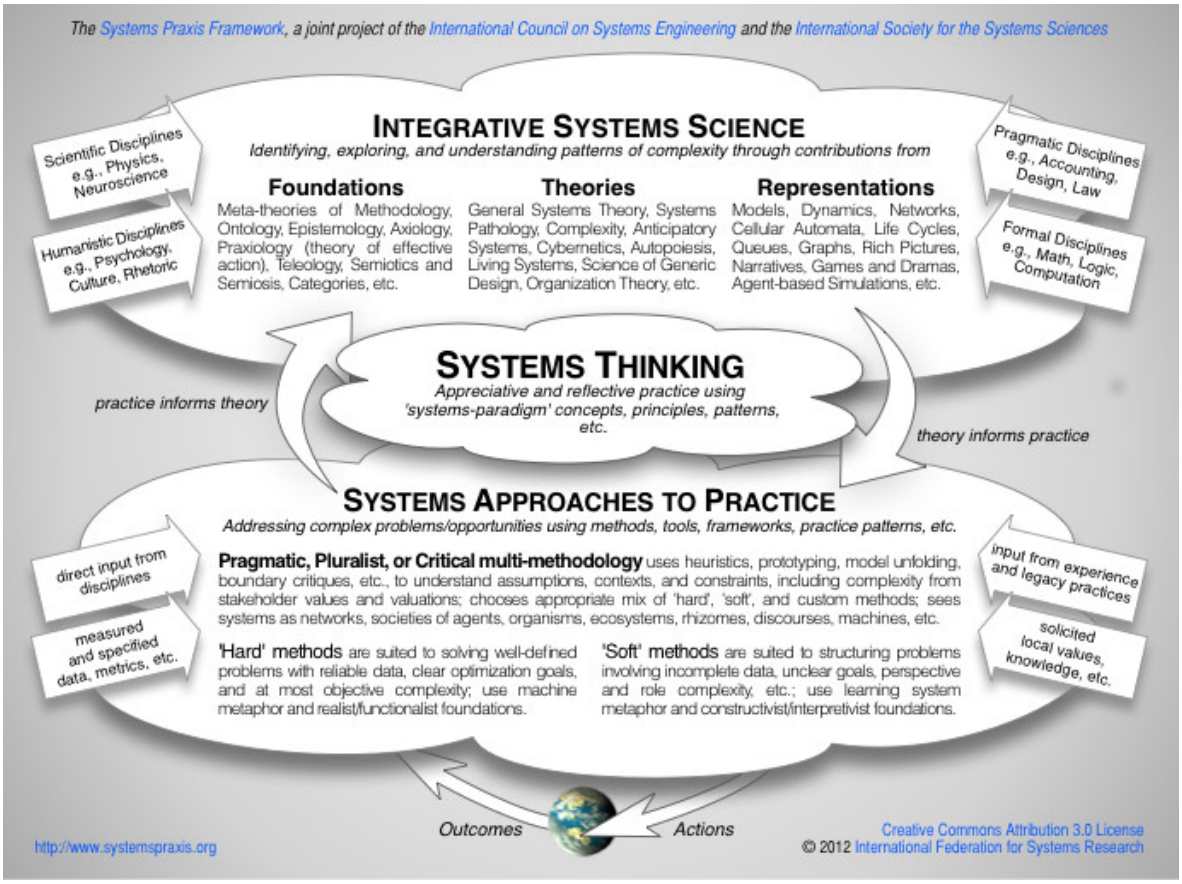

Figure 2. The Systems Praxis Framework, Developed as a Joint Project of INCOSE and ISSS. (© 2012 International Federation for Systems Research) Released under Creative Commons Attribution 3.0 License. Source is available at http://systemspraxis.org/framework.pdf.

In this framework, the following elements are connected:

Systems Thinking is the core integrative element. It connects the foundations, theories, and representations of systems science with the hard, soft, and pragmatic approaches of systems practice. Like any discipline underpinned by science, systems praxis involves a continuous interplay between theory and practice: theory informs practice, and

practice generates insights that refine theory. Systems thinking provides the ongoing capability to assess and appreciate the system context, and to guide appropriate adaptation throughout the praxis cycle.

Integrative Systems Science provides the conceptual base and is grouped into three broad areas:

- *Foundations*, organizing knowledge and supporting discovery (e.g., methodology, ontology, epistemology, axiology, praxiology, teleology, semiotics, category theory).
- *Theories*, abstracted from specific domains but universally applicable (e.g., general system theory, complexity, anticipatory systems, cybernetics, autopoiesis, living systems, design science, organization theory, systems pathology).
- *Representations*, models and formalisms for describing, analyzing, and predicting system behaviors and contexts (e.g., system dynamics, networks, cellular automata, life cycles, graphs, rich pictures, narratives, games, agent-based simulations).

Systems Approaches to Practice aim to act on real-world situations to produce desired outcomes while minimizing unintended consequences. No single branch of systems science or practice is sufficient for every problem; therefore, a pragmatic blend is often required:

- *Hard approaches* are suited to well-defined problems with clear goals and reliable data. They emphasize quantitative analysis, optimization, and technical systems, often grounded in “machine” metaphors.
- *Soft approaches* are suited to problems with incomplete data, ambiguous goals, and social complexity. They emphasize learning, communication, and multiple perspectives, drawing from “humanist” philosophies.
- *Pragmatic approaches* combine elements of both, selecting methods, tools, and heuristics as appropriate to the situation. This includes techniques such as boundary critique or model unfolding, enabling diverse stakeholders to make assumptions and constraints explicit.

The “clouds” that collectively represent systems praxis sit within a wider **ecosystem of knowledge, learning, and action**. Successful integration requires drawing on the sciences (e.g., physics, neuroscience), formal disciplines (e.g., mathematics, logic, computation), the humanities (e.g., psychology, culture, rhetoric), and pragmatic fields (e.g., accounting, design, law). Systems practice depends not only on theories and models, but also on data, metrics, local knowledge, and lived experience.

In summary, integrative systems science provides the concepts and patterns that allow us to understand complexity, while systems approaches to practice apply these insights to address real problems. Systems thinking binds them together, creating an adaptive cycle of theory and practice that underpins all systems engineering foundations.

Scope of Part 2

Part 2 of the SEBoK provides a guide to systems knowledge that is most relevant for understanding and practicing systems engineering. It does not attempt to capture the entirety of systems science or systems practice. Instead, it offers an overview of key aspects of systems theory and application that are especially important for systems engineers.

The organization of Part 2 is based on the *Systems Praxis Framework* (IFSR 2012), which emphasizes the need for a clear and shared foundation to support effective communication and collaboration across diverse domains. As the discipline evolves, it is expected that the coverage of systems knowledge in Part 2 will continue to expand.

The following diagram summarizes the way in which the knowledge in SEBoK Part 2 is organized..

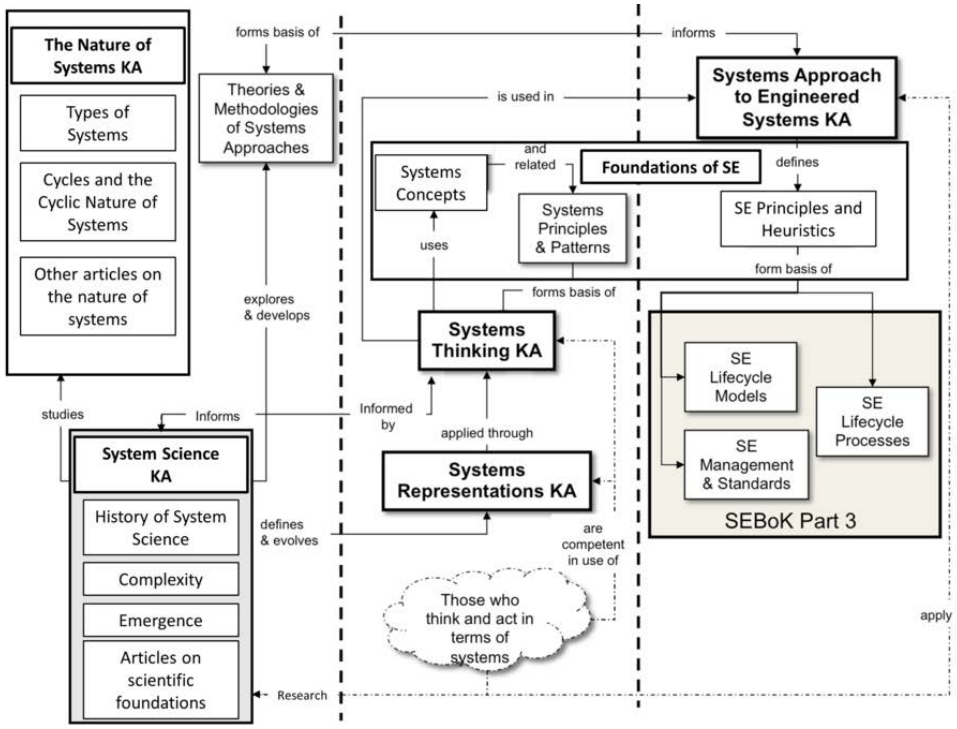

Figure 3. The Relationships between Key Systems Ideas and SE. (SEBoK Original)

The six Knowledge Areas in Part 2 each highlight a different but complementary aspect of systems foundations:

1. Systems Fundamentals, introduces essential definitions, concepts, principles, and heuristics. These provide systems engineers with a baseline vocabulary and the means to distinguish different kinds of systems, including product, service, enterprise, and system-of-systems,
2. The Nature of Systems, surveys the diversity of natural, engineered, and socio-technical systems, drawing attention to universal patterns that underpin systems science and form the basis of systems thinking and systems engineering.
3. Systems Science, presents influential theories and movements in systems research, including the chronological development of systems knowledge and the foundations that inform systems approaches.
4. Systems Thinking, describes the perspectives, principles, and patterns that characterize a systemic worldview. It emphasizes the role of reflective practitioners who integrate research and practice in order to frame and address complex problems.
5. Representing Systems with Models, considers the central role of models in both advancing systems theory and supporting engineering practice, from conceptual understanding to design and analysis..
6. Systems Approach Applied to Engineered Systems, defines a structured approach for problem and opportunity discovery, solution synthesis, analysis, implementation, and use. This knowledge area provides the most direct link between systems foundations and practical SE application.

Taken together, these Knowledge Areas form a **"system of ideas"** that connects research, understanding, and practice. They provide a shared foundation of systems knowledge that underpins a wide range of scientific, management, and engineering disciplines, and that can be applied across all types of domains.

This knowledge area (KA) provides a guide to some of the most important knowledge about system engineering fundamentals. System Engineering benefits from systems thinking in combination with an essential understanding of The Nature of Systems. It applies systems approaches to practice grounded in systems science.

This is part of the wider systems knowledge, which can help to provide a common language and intellectual foundation and make practical systems concepts, principles, patterns and tools accessible to systems engineering (SE) as discussed in Part 2: Foundations of Systems Engineering.

Introduction

A concept is a mental representation that can be shared with a word or other media such as visualizations, pictures or displays of emotion (Daniel-Allegro B, Smith G.R. 2016). Systems Engineering Core Concepts provide the mental building blocks that when brought together can support an expression of principles. “A principle is a fundamental truth or proposition that serves as the foundation for a system of belief or behavior or for a chain of reasoning”. As an example, if you have three colors, red, blue, yellow (all words that serve as mental concepts). A principle is if you mix some yellow with some blue then you get green. A principle can provide guidance for acting with some certainty of the result. Principles learnt from practical experience that yet lack a scientific understanding as to the explanation of “why” are referred to as heuristics. Often in the progression of science these observations of ‘what is happening’ form the starting point for asking the question ‘why does this happen’ and prompts research into the underpinning scientific theory.

The evolution of Systems Engineering Heuristics and associated Systems Engineering Principles is described. The objective of system science is to provide the theoretical basis for these principles (the 'why' behind the phenomena).

The word system is a concept used in many areas of human activity and at many levels. But what do System Engineers mean when they use the word system? The answer is surprisingly not as simple as you might think.

(Sillitto, Griego et al. 2018) established in their research that there are at least seven distinct, and to a considerable extent mutually incompatible, worldviews on systems within a relatively small population of systems engineering experts in the INCOSE Fellows' and System Science Working Group (SSWG) communities. The worldviews identified ranged from constructivist ("systems are purely a mental construct") to "extreme realist" ("systems only exist in the real world"). Some considered the threshold of systemness" to be as simple as "two or more inter-related elements"; while others demanded a wide range of attributes, including those of living systems, before considering something to be a system.

That such a wide range of worldviews was discovered within the Systems Engineering community was a surprising result. We might expect to find an even wider range of worldviews across a more diverse community; but a non-rigorous examination of the results of the survey and of the wider literature suggests that the range of "system" worldviews held by the surveyed group of Systems Engineers is broadly representative of the systems field. In the 2019 IFSR conversation "What is System Science?" (Metcalf, G.S, Edson M.C, and Chroust G. 2018), it was concluded that there would be great benefit to achieve a synthesis across the apparently conflicting worldviews of constructivism and realism, expressed in terms of these two key aspects: a) the nature of systems in the physical universe; and b) the way humans perceive and interact with systems.

The philosophical foundations of systemness and system research are described (M.C Edson, Henning P, Sankaran. 2017), this work provides a meta-theoretical orientation of systems and an orientation for systems research processes and practices.

In practical terms, in the Introduction to Systems Engineering Fundamentals, the concepts of open system and closed system are explored. Open systems, described by a set of elements and relationships, are used to describe many real world phenomena. Conceptually closed systems have no interactions with their environment.

Some systems classifications, characterized by type of element or by purpose, are presented.

An engineered system is defined within the SEBoK as encompassing combinations of technology and people in the context of natural, social, business, public or political environments, created, used and sustained for an identified purpose. The application of the Systems Approach Applied to Engineered Systems requires the ability to position problems or opportunities in the wider system containing them, to create or change a specific engineered system-of-interest, and to understand and deal with the consequences of these changes in appropriate wider systems. The concept of a system context allows all of the system elements and relationships needed to support this to be identified.

Two particular aspects of the system phenomena complexity and emergence, are described in the System Science KA. Between them, these two concepts represent many of the challenges which drive the need for systems thinking and an appreciation of systems science in SE. In The Nature of Systems KA, a rich portrayal of the landscape of systems and the system phenomena is provided.

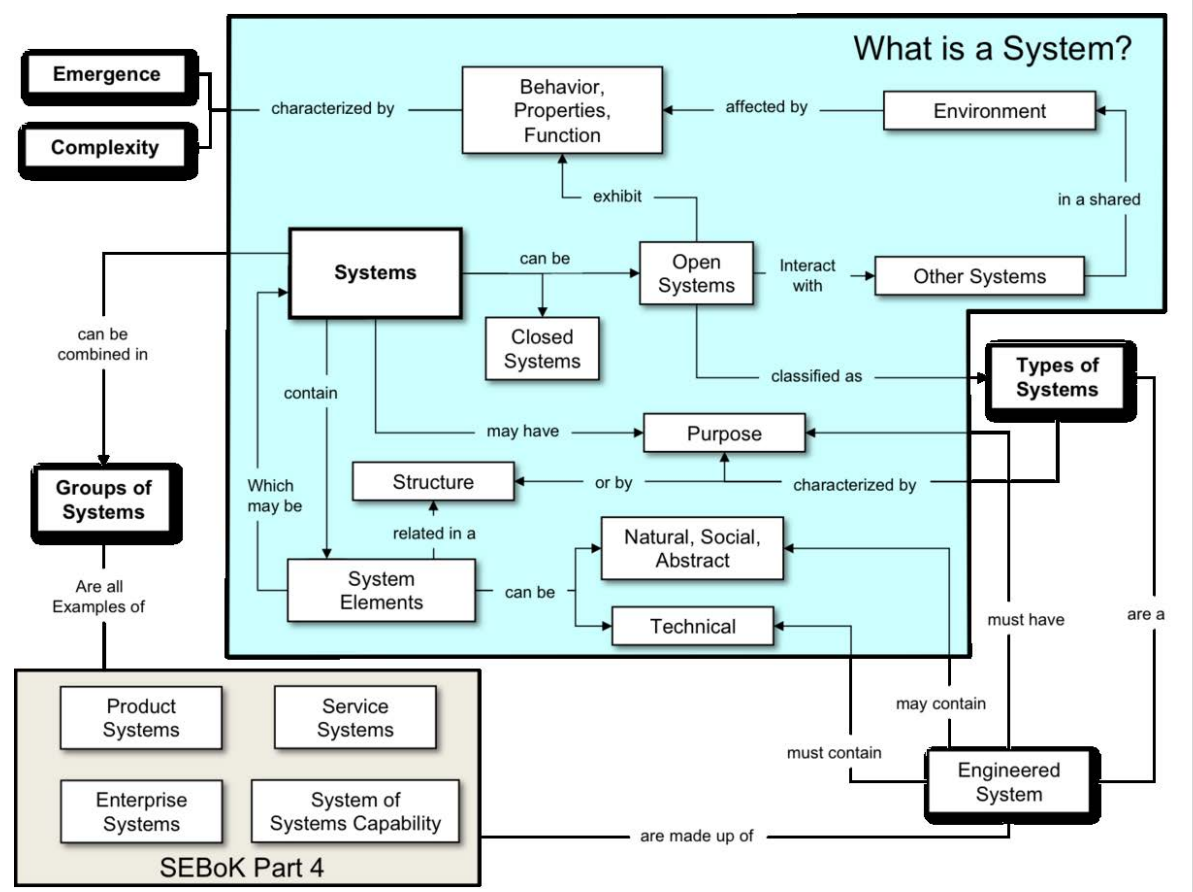

Figure 1. System Fundamentals and Engineered Systems. (SEBoK Original)

The discussions of engineered system contexts includes the general idea of groups of systems to help deal with situations in which the elements of an engineered system are themselves independent engineered systems. To help provide a focus for the discussions of how SE is applied to real world problems, four engineered system contexts are introduced in the KA:

1. product system context
2. service system context
3. enterprise system context
4. system of systems (sos) context

The details of how SE is applied to each of these contexts are described in Part 4: Applications of Systems Engineering.

Introduction to Systems Engineering Fundamentals

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Brian Wells, Scott Jackson, Janet Singer, and Duane Hybertson

-

This article forms part of the Systems Fundamentals knowledge area (KA). It provides various perspectives on systems, including definitions, scope, and context.

This article provides a guide to some of the basic concepts of systems developed by systems science and discusses how these relate to the definitions to be found in systems engineering (SE) literature. The concept of an engineered system is introduced as the system context of critical relevance to SE.

Overview

In the System Fundamentals KA we will define some terms and ideas which are foundational to the understanding and practice of Systems Engineering (SE). In particular, a number of views of system are explored; these are summarized below and described in more detail with links to relevant references in the rest of this article.

- The INCOSE Fellows’ Initiative on System and Systems Engineering Definitions [1] expresses that "**A system is an arrangement of parts or elements that together exhibit behaviour or meaning that the individual constituents do not"**. The premise of the system phenomena and the basis for system science is that there are theories, models and approaches that are transversal and useful to anyone trying to understand, create, transform or experience systems, independent of what the system is made of or the application domain considering it.
- Systems can be either physical or conceptual, or a combination of both. Systems in the physical universe are composed of matter and energy, may embody information encoded in matter-energy carriers, and exhibit

observable behaviour. Conceptual systems are abstract systems of pure information, and do not directly exhibit behaviour, but exhibit "meaning". In both cases, the system's properties (as a whole) result, or emerge from: the parts or elements and their individual properties; AND the relationships and interactions between and among the parts, the system and its environment.

- Many of these common systems ideas relate to complex networks or hierarchies of related system elements. A **System Context is a set of system interrelationships associated with a particular system of interest (SoI) within a real world environment**. One or more views of a context allow us to focus on the SoI but not lose sight of its broader, holistic relationships and influences. Context can be used for many kinds of system but is particularly useful for scoping problems and enabling the creation of solutions which combine people and technology and operate in the natural world. These are referred to as socio-technical system contexts.
- Systems Engineering is one of the disciplines interested in socio-technical systems across their whole life. This includes where problems come from and how they are defined, how we identify and select candidate solutions, how to balance technology and human elements in the wider solution context, how to manage the complex organizational systems needed to develop new solutions, and how developed solutions are used, sustained and disposed of. To support this, we define an **Engineered System as a socio-technical system which is the focus of a Systems Engineering life cycle.**
- While SE is focused on the delivery of an engineered system of interest, an **SE should consider the full Engineered System Context so that the necessary understanding can be reached and the right systems engineering decisions can be made across each Life Cycle.**

A General View of Systems

The idea of a system whole can be found in both Western and Eastern philosophy. Many philosophers have considered notions of holism, the concept that ideas, people or things must be considered in relation to the things around them to be fully understood (M'Pherson 1974). Broader still, the concept of holarchy, that everything in the universal is an organized whole (a system) and also at the same time a part of a, at least one, greater whole (Koestler 1967).

One influential systems science definition of a system comes from general system theory (GST):

> *A System is a set of elements in interaction.* (Bertalanffy 1968)

The parts of a system may be conceptual organizations of ideas in symbolic form or real objects. GST considers **abstract systems** to contain only conceptual elements and **concrete systems** to contain at least two elements that are real objects, e.g. people, information, software, and physical artifacts, etc.

Similar ideas of wholeness can be found in systems engineering literature. For example:

> *We believe that the essence of a system is 'togetherness', the drawing together of various parts and the relationships they form in order to produce a new whole…* (Boardman and Sauser 2008).

The cohesive interactions between a set of parts suggest a system boundary and define what membership of the system means. For **closed systems**, all aspects of the system exist within this boundary. This idea is useful for abstract systems and for some theoretical system descriptions.

The boundary of an **open systems** defines elements and relationships which can be considered part of the system and describes how these elements interact across the boundary with related elements in the environment. The relationships among the elements of an open system can be understood as a combination of the systems structure and behavior. The structure of a system describes a set of system elements and the allowable relationships between them. System behavior refers to the effects or outcomes produced when an instance of the system interacts with its environment. An allowable configuration of the relationships among elements is referred to as a system state. A stable system is one which returns to its original, or another stable, state following a disturbance in the environment. *System wholes entities often exhibit emergence, behavior which is meaningful only when attributed to the whole, not*

to its parts (Checkland 1999).

The identification of a system and its boundary is ultimately the choice of the observer, the recognition of a system and to establish a relation with it is a decision made cognitively such as by a human actor or through affordances through physical relationships in the case of chemical substances. In the case of humans, this may be through observation and classification of sets of elements as systems, through an abstract conceptualization of one or more possible boundaries and relationships in a given situation, or a mixture of this concrete and conceptual thinking. This underlines the fact that any particular identification of a system by humans is a construct used by us to help make better sense of a set of things and to share that understanding with others if needed. It is important to recognize that this notion of observer is not limited to human perception. The observation and development of relationships between systems is a natural phenomena inherent in all systems.

Many natural, social and man made things can be better understood by recognising the subjects of our interest as open systems as this takes into account this key dependency with the external, such as the stakeholder or actors with these systems. Additionally, one of the reasons we find the transversal nature of systems useful is that it is possible to identify shared concepts which apply to many system views. These recurring concepts or isomorphies can give useful insights into many situations, independently of the kinds of elements of which a particular system is composed. The ideas of structure, behavior, emergence and state are examples of such concepts. The identification of these shared system ideas is the basis for systems thinking and their use in developing theories and approaches in a wide range of fields of study the basis for system sciences.

Systems Engineering (SE), and a number of other related disciplines use systems concepts, patterns and models in the creation of useful outcomes or things. The concept of a network of open systems created, sustained and used to achieve a purpose within one or more environments is a powerful model that can be used to understand many complex real world situations and provide a basis for effective problem solving within them.

System Context

Bertalanffy (1968) divided open systems into nine real world types ranging from static structures and control mechanisms to socio-cultural systems. Other similar classification systems are discussed in the article Engineered Systems.

The following is a simple classification of system elements which we find at the heart of many of these classifications:

- Natural system elements, objects or concepts which exist outside of any practical human control. Examples: the real number system, the solar system, planetary atmosphere circulation systems.
- Social system elements, either abstract human types or social constructs, or concrete individuals or social groups.
- Technological System elements, man-made artifacts or constructs; including physical hardware, software and information.

While the above distinctions can be made as a general abstract classification, in reality there are no hard and fast boundaries between these types of systems: e.g., natural systems are operated by, developed by, and often contain social systems, which depend on technical systems to fully realize their purpose. Systems which contain technical and either human or natural elements are often called socio-technical systems. The behavior of such systems is determined both by the nature of the technical elements and by their ability to integrate with or deal with the variability of the natural and social systems around them.

Many of the original ideas upon which GST and other branches of system study are based come from the study of systems in the natural and social sciences. Many natural and social systems are initially formed as simple structures through the inherent cohesion among a set of elements. Once formed, they will tend to stay in this structure, as well as combine and evolve further into more complex stable states to exploit this cohesion in order to sustain themselves in the face of threats or environmental pressures. Such complex systems may exhibit specialization of elements, with

elements taking on roles which contribute to the system purpose, but losing some or all of their separate identity outside the system. Such roles might include management of resources, defense, self-regulation or problem solving, and control. Natural and social systems can be understood through an understanding of this wholeness, cohesion and specialization. They can also be guided towards the development of behaviors which not only enhance their basic survival, but also fulfill other goals of benefit to them or the systems around them. In *The Architecture of Complexity,* Simon (1962) has shown that natural or social systems which evolve via a series of stable "hierarchical intermediate forms" will be more successful and resilient to environmental change.

Thus, it is often true that the environment in which a particular system sits and the elements of that system can themselves be considered as open systems. It can be useful to consider collections of related elements as both a system and a part of one or more other systems. For example, a "holon" or system element was defined by Koestler as something which exists simultaneously as a whole and as a part (Koestler 1967). At some point, the nature of the relationships between elements within and across boundaries in a hierarchy of systems may lead to complex structures and emergent behaviors which are difficult to understand or predict. Such complexity can often best be dealt with not only by looking for more detail, but also by considering the wider open system relationships.

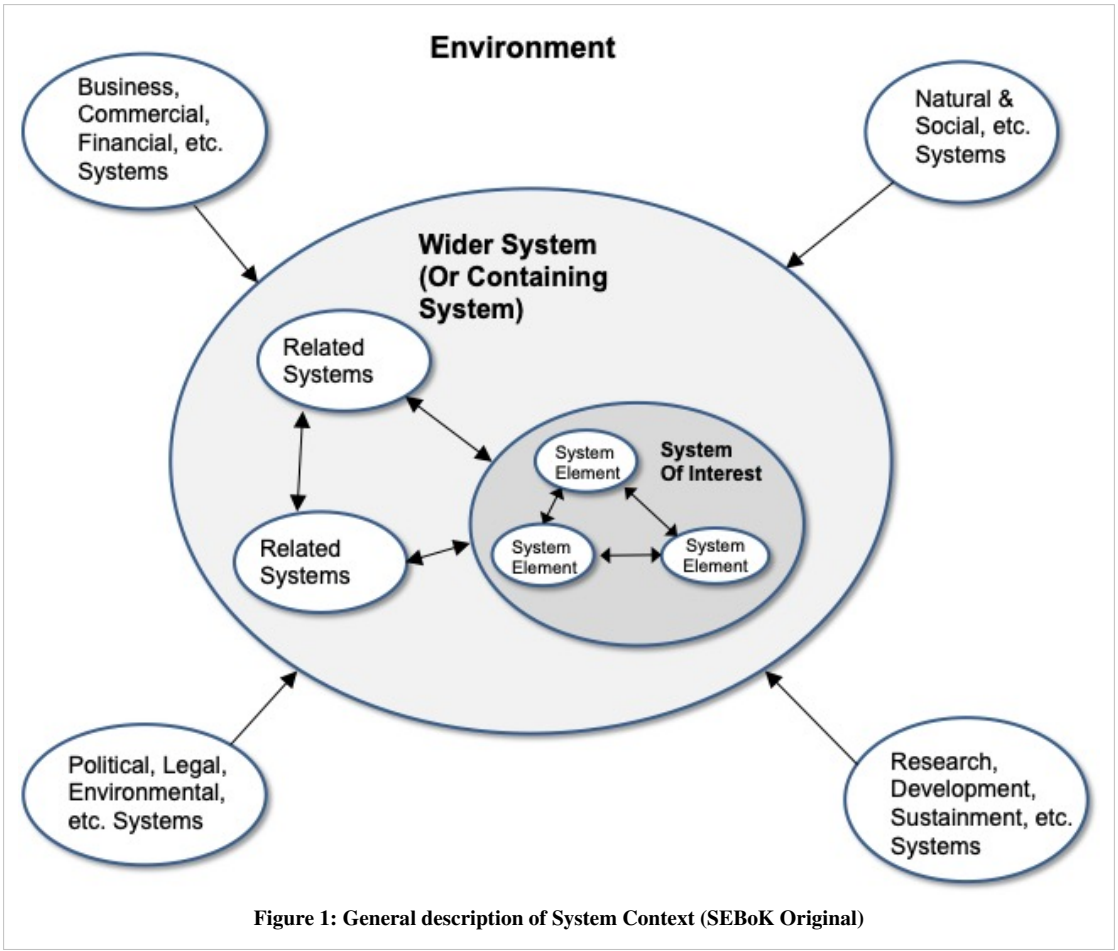

Figure 1: General description of System Context (SEBoK Original)

A system context describes all of the external elements which interact across the boundary of a particular system of interest (SoI) and a sufficient view of the elements within its boundary, to allow the SoI to be better understood as part of a wider systems whole. To fully understand the context, we also need to identify the environment in which the SoI and wider system sit and the systems in the environment which influence them.

Many man-made systems are designed as networks and hierarchies of related system elements to achieve desirable behaviors and the kinds of the resilience seen in natural systems. While such systems can be deliberately created to take advantage of system properties such as holism and stability, they must also consider system challenges such as complexity and emergence. Considering different views of a SoI and its context over its life can help enable this

understanding. Considering systems in context allows us to focus on a SoI while maintaining the necessary wider, holistic systems perspective. This is one of the foundations of the Systems Approach described in SEBoK part 2, which forms a foundation of systems engineering.

Systems and Systems Engineering

Some of the systems ideas discussed above form part of the systems engineering body of knowledge. Systems engineering literature, standards and guides often refer to “the system” to characterize a socio-technical system with a defined purpose as the focus of SE, e.g.

- “A system is a value-delivering object” (Dori 2002).
- “A system is an array of components designed to accomplish a particular objective according to plan” (Johnson, Kast, and Rosenzweig 1963).
- “A system is defined as a set of concepts and/or elements used to satisfy a need or requirement" (Miles 1973).

The International Council on Systems Engineering Handbook (INCOSE 2015) generalizes this idea, defining system as “an interacting combination of elements to accomplish a defined objective. These include hardware, software, firmware, people, information, techniques, facilities, services, and other support elements." While these definitions cover the socio-technical systems created by SE, it is also necessary to consider the natural or social problem situations in which these systems sit, the social systems which developed, sustained and used them, and the commercial or public enterprises in which these all sit as systems (Martin 2004).

Hence, while many SE authors talk about systems and systems ideas, they are often based on a particular world view which related to engineered artifacts. It would also be useful to take a broader view of the context in which these artifacts sit, and to consider through life relationships as part of that context. To help promote this, the SEBoK will attempt to be more precise with its use of the word system, aligned with the work of the fellows initiative and distinguish between general systems principles and the specific socio-technical systems created by SE.

The term socio-technical system is used by many in the systems community and may have meanings outside of that relevant to SE. Hence, we will define an engineered system as a socio-technical system which forms the primary focus or system of interest (SoI) for an application of SE. A SE life cycle will consider an engineered system context, from initial problem formulation through to final safe removal from use (INCOSE 2015). A more detailed discussion of engineered system context and how it relates to the foundations of systems engineering practice can be found below.

Introduction to Engineered Systems

An engineered system defines a context containing both technology and social or natural elements, developed for a defined purpose by an engineering life cycle.

Engineered system contexts:

- are created, used and sustained to achieve a purpose, goal or mission that is of interest to an enterprise, team, or an individual.
- require a commitment of resources for development and support.
- are driven by stakeholders with multiple views on the use or creation of the system, or with some other stake in the system, its properties or existence.
- contain engineered hardware, software, people, services, or a combination of these.
- exist within an environment that impacts the characteristics, use, sustainment and creation of the system.

Engineered systems typically:

- are defined by their purpose, goal or mission.
- have a life cycle and evolution dynamics.

- may include human operators (interacting with the systems via processes) as well as other social and natural components that must be considered in the design and development of the system.
- are part of a system-of-interest hierarchy.

Open systems are a useful way to understand many complex situations. Traditional engineering disciplines have become very good at building up detailed models and design practices to deal with the complexity of tightly integrated collections of elements within a technology domain. It is possible to model the seemingly random integration of lots of similar elements using statistical approaches. Systems Engineering makes use of both these aspects of system complexity, as discussed in the Complexity article.

SE also considers the complexity of relatively small numbers of elements taken from a range of design disciplines together with people who may not always be experienced or have detailed training in their use. Such engineered systems may be deployed in uncertain or changing environments and be used to help people achieve a number of loosely defined outcomes. Relatively small changes in the internal working of these engineered systems' elements, or in how those elements are combined, may lead to the emergence of complex or un-expected outcomes. It can be difficult to predict and design for all such outcomes during an engineered system's creation, or to respond to them during its use. Iterative life cycle approaches which explore the complexity and emergence over a number of cycles of development and use are needed to deal with this aspect of complexity. The ways that system engineering deals with these aspects of complexity in the definition of life cycle and life cycle processes applied to an engineered system context is fully explored in Part 3

Life Cycle Definitions

As well as being a kind of system, an engineered system is also the focus of a life cycle and hence part of a commercial transaction. Historically,

> *Economists divide all economic activity into two broad categories, goods and services. Goods-producing industries are agriculture, mining, manufacturing, and construction; each of them creates some kind of tangible object. Service industries include everything else: banking, communications, wholesale and retail trade, all professional services such as engineering, computer software development, and medicine, nonprofit economic activity, all consumer services, and all government services, including defense and administration of justice....* (Encyclopedia Britannica 2011).

The following diagram defines some terms related to an engineered system life cycle and the development of goods (products) and services.

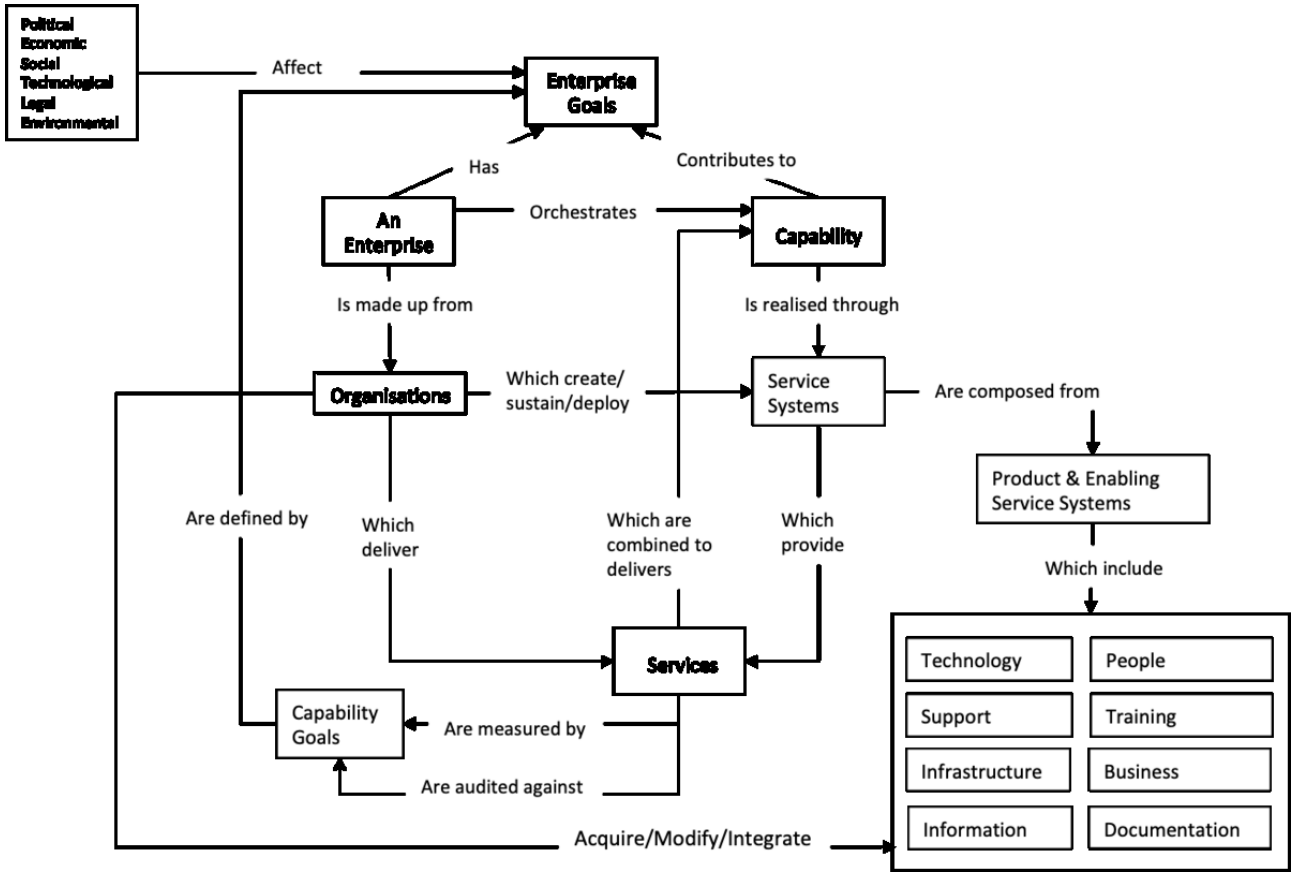

Figure 2: Life Cycle Terminology (Modified from Capability Engineering – an Analysis of Perspectives (modified from (Henshaw et al, 2011), used with permission))

In the above figure the capability needed to enable an enterprise to achieve its goals is delivered by the synchronized use of services. Those services are provided by a service system ,which is created, sustained and deployed by one or more organizations. A service system is composed of people, technology, information, and access to related services and other necessary resources. Some of these resources are provided by enabling services and the technological elements may be developed and supplied as product systems. An enterprise system describes a collection of related capabilities and associated services which together enable the achievement of the overall purpose of an enterprise as a government, business or societal entity. Measurement and review of enterprise goals may define needs for change which require an organization to acquire or modify, and integrate the elements needed to evolve its service systems. The general terminology above is described briefly in the associated glossary definitions and expanded in related articles in Part 4: Applications of Systems Engineering.

Engineered System Context

Engineered systems are developed as combinations of products and services within a life cycle. The figure below gives a general view of the full context for any potential application of a SE life cycle.

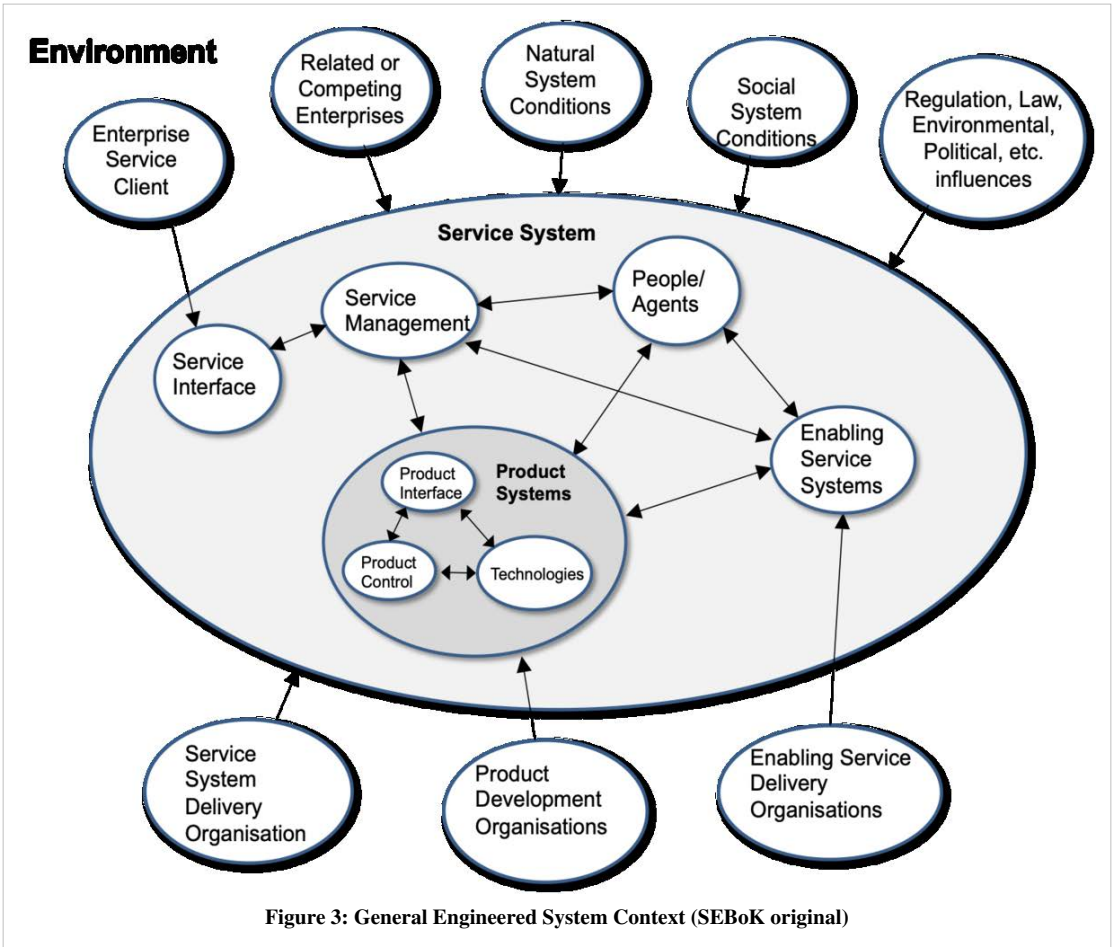

Figure 3: General Engineered System Context (SEBoK original)

In this view a service system related directly to a capability need sets the overall boundary. This need establishes the problem situation or opportunity which encapsulates the starting point of any life cycle. Within this service system are the related services, products and people (or intelligent software agents) needed to fully deliver a solution to that need. The environment includes any people, organizations, rules or conditions which influence or constrain the service system or the things within it. The SoI for a particular SE life cycle may be defined at any level of this general context. While the focus of the context will vary for each life cycle it is important that some version of this general context is considered for all SE life cycles, to help maintain a holistic view of problem and solution. This is discussed in Engineered Systems.

An engineered system context describes the context for a SoI so that the necessary understanding can be reached and the right systems engineering decisions can be made across the life of that SoI. This will require a number of different views of the context across a SE life cycle, both to identify all external influence on the SoI and to guide and constraint the systems engineering of the elements of the SoI. A full engineered systems context will include the problem situation from which a need for a SoI is identified, one or more socio technical solutions, the organizations needed to create and sustain new solutions and the operational environment within which those solutions must be integrated, used and eventually disposed. The kinds of views which can be used to represent a SoI context over its life and how those views can be combined into models is discussed in the Representing Systems with Models KA in Part 2. The activities which use those models are described conceptually in the Systems Approach Applied to Engineered Systems KA in part 2 and related to more formal SE life cycle processes in Part 3.

This article is part of the *Foundations of Systems Engineering* knowledge area. It integrates core **systems engineering** concepts, as presented in the SEBoK article *Systems Engineering Core Concepts*, with a general system model derived from **systems science**. The purpose is to enrich the conceptual foundation of systems engineering by showing how recent formal developments in systems science offer deeper theoretical structure to existing SE constructs. The integration is grounded in George Mobus's axiomatic model (Mobus 2022), which provides mathematical formalisms for systems structure and behavior. This article shows how these axioms can underpin and clarify SE concepts such as the System-of-Interest, System Context, Life Cycle Process, and *Emergence*. It also provides a generalized system model that enables consistency between conceptual understanding and quantitative modeling.

Concepts are the fundamental building blocks for the construction of theories, principles, thoughts and beliefs. They play an important role in all aspects of cognition and communication.

Purpose and Uses of the Systems Engineering Concept Model

The Systems Engineering Concept Model (SECM) captures the concepts that are referred to in the Systems Engineering Body of Knowledge. The SECM provides a means to evaluate the consistency and coverage across the broad set of Systems Engineering concepts, and can facilitate communication to better understand and evolve these concepts. Although the primary reference for the SECM was the SEBoK, the concepts were cross-checked against other industry references including ISO/IEC/IEEE 15288:2015 and the INCOSE Systems Engineering Handbook version 5, enabling the SECM to be used to evaluate, understand, and evolve the concepts in these references as well. A small team developed the SECM to support the requirements for the next generation of the OMG Systems Modeling Language (OMG SysML™) to ensure SysML is consistent with the three leading industry standards.

SECM Approach

A concept model, called the Concept Map, was developed by the original SEBoK team prior to release of the SEBoK v1.0 in 2012 and was used to support integration of the initial concepts across the SEBoK topic areas. The Concept Map included a concept model and a mapping of the concepts to the glossary terms and to the sections of the SEBoK.

The SECM captures the Systems Engineering concepts and their relationship that are contained in today's SEBoK. The small subset of UML constructs and symbols, shown in Figure 1, are used to represent the SECM model. The choice of notations is intended to balance simplicity, understandability, and precision.

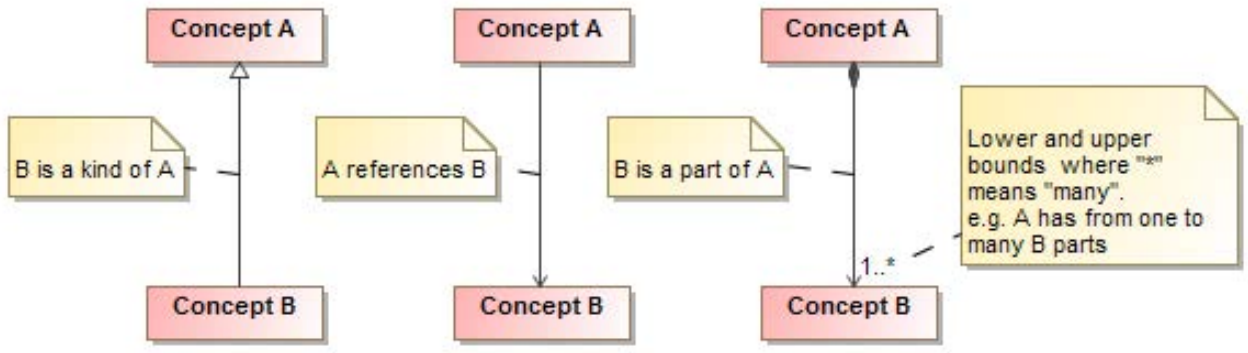

Figure 1. Concept Relationships used in the SECM. (SEBoK Original)

Figure 2 below shows a usage of these constructs and symbols when applied to a simple example of a Car. This diagram shows that a Car is kind of a Vehicle, and that the Driver drives the car (a reference relationship), and that there are four wheels that are parts of the Car.

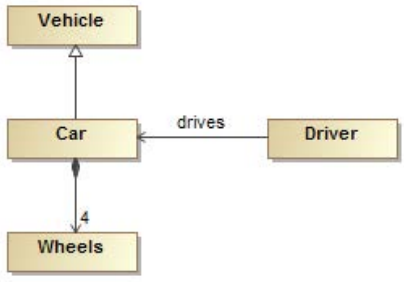

Figure 2. Example of Relationships between Concepts (SEBoK Original)

The SECM is presented in a series of diagrams that generally represent concepts for particular knowledge areas and topics in the SEBoK, and also includes references to glossary terms in the SEBoK.

The approach used to capture the SECM content from the SEBoK is described in the following steps:

1. A topic within a SEBoK knowledge area is selected and the text is evaluated to identify key Systems Engineering concepts.
2. From the sentences containing the concepts, the subjects, i.e. the concepts, and the predicate, i.e. the relationship between concepts, are identified. The predicate is a statement that says something about the subject.
3. A search is conducted for this concept in other areas of the SEBoK, and the accompanying text is evaluated to further refine the concept and its relationships to other concepts.
4. The definition of the concept in the SEBoK glossary, if available, is evaluated.
5. The use and definition of this concept in the other two industry references is evaluated.
6. The concept and a derived definition from the above evaluation are added to the SECM.
7. The discovered relationships between the concepts are added to the model and to the relevant diagrams. The diagrams group related concepts that are often associated with a SEBoK Knowledge Area or Topic.
8. As new contributions are made to the SEBoK, this approach can be used to identify new concepts and relationships, and add them to the SECM.

Introduction to Core Concepts

The SECM was developed independently of the BKCASE project to support the evolution of the SysML standard. These models can be used to identify inconsistencies and/or areas requiring additional coverage within the SEBoK to support future updates.

The Core Concept Diagram shown in Figure 3 provides a high-level view of the some of the key concepts presented in the SEBoK. It should be emphasized that this figure is intended to be a representative interpretation of the current SEBoK without modifying or adding concepts, and no claim of the completeness of the SEBoK concepts is made. The colors correspond to logical groupings of concepts.

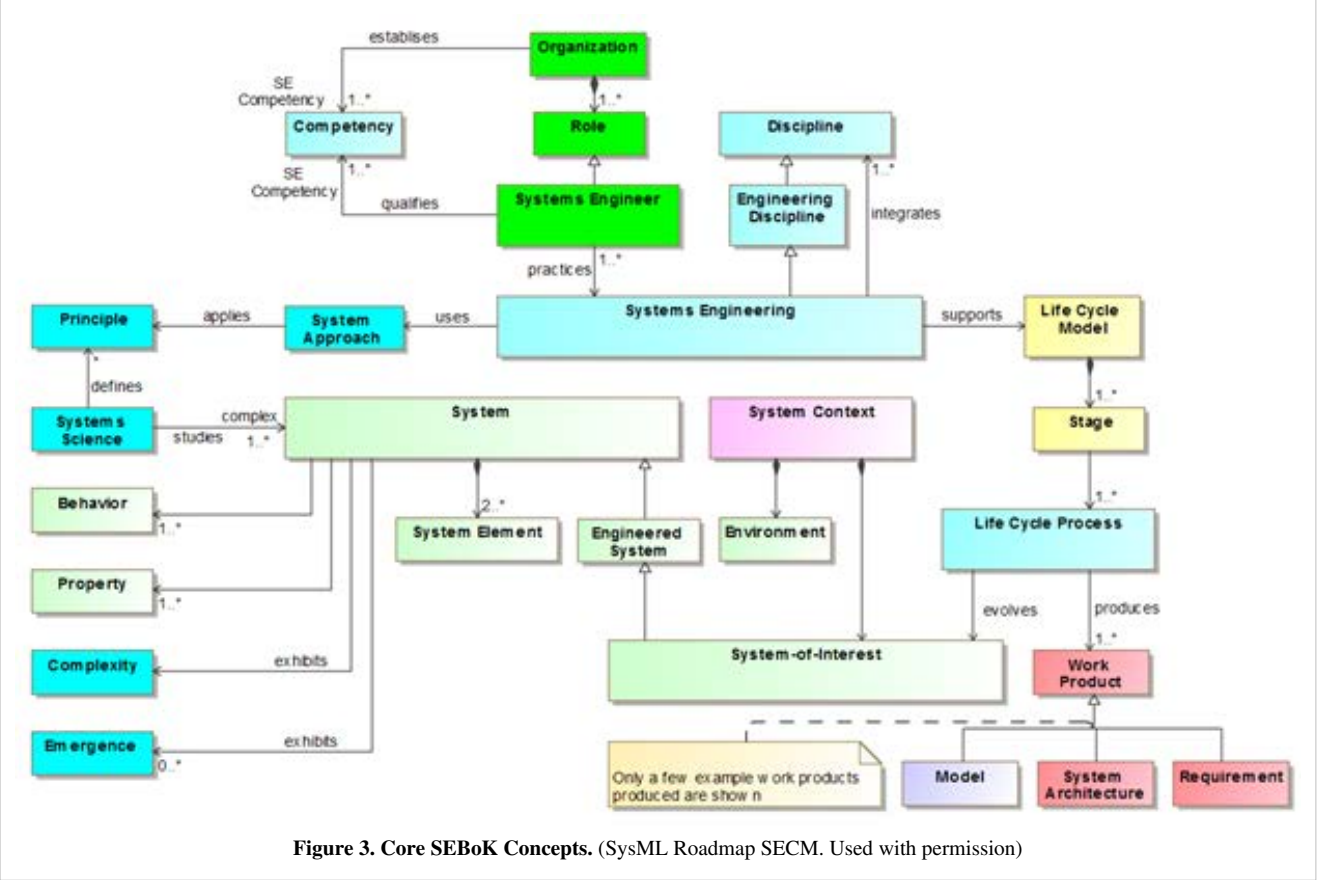

Figure 3. Core SEBoK Concepts. (SysML Roadmap SECM. Used with permission)

A brief description of the core concepts model is provided below.

A *Systems Engineer* is a role within an *Organization* that practices the *Engineering Discipline of Systems Engineering* (SE), and is qualified by a set of SE *Competencies*. *Systems Engineering* integrates other *Disciplines* to support the *Life Cycle Model*. The Life Cycle Model is composed of life cycle *Stages* that typically include conceptual, realization, production, support, utilization and retirement stages (not shown). Each life cycle *Stage* refers to *Life Cycle Processes* that produce various kinds of *Work Products*. The *Life Cycle Processes* evolve the *System-of-Interest* (SoI).

There are many kinds of systems, including natural systems, social systems, and technological systems (not shown). Systems that are created by and for people are referred to as *Engineered Systems*. An *Engineered System* whose life cycle is under consideration is referred to as a System-of-Interest (SoI).

A System-of-Interest is part of a broader *System Context*, which also includes an *Environment*. The Environment consists of other open systems (not shown) that can influence the SoI. Systems are composed of System Elements and have Behavior and Properties. Systems can exhibit *Emergence* and *Complexity*.

Systems Engineering uses a *System Approach* which applies established system *Principles*. *Systems Science* is an interdisciplinary field of science that studies complex systems and helps define and update the *Principles* that are

applied by the *System Approach*, which is used by the discipline of Systems Engineering.

Axiomatic Foundations from Systems Science

Mobus (2022) introduces a formal system model expressed as: Si,l = C,N,G,B,T,H,Δti,l

This model includes:

C: Components

N: Internal network structure

G: External interaction graph (context/environment)

B: System boundary and interface

T: Transformation functions (behavior)

H: System history (state evolution)

These map to axioms that characterize system properties:

Relationality: Components interact through measurable flows, creating a network of quantifiable relationships.

Hierarchy: Systems decompose recursively into simpler subsystems until reaching atomic components.

Context & environment: Systems interact with their environment through defined interfaces and measurable flows.

Emergence & holism: System behaviors arise from component interactions and transformations across levels.

Feedback: Information and material flows create regulatory patterns through circular causation.

Conservation & transformation: Systems maintain and transform flows while preserving conservation laws.

Integrating SEBoK Concepts with Systems Science

The following table maps SEBoK concepts to Mobus's axiomatic framework:

SEBoK Concept	Mobus Element	Description
System-of-Interest (SoI)	S_{i,l}	The engineered system modeled as a whole
System Elements	C	Components forming the system
Internal Relationships	N	Networked structure of interactions
Environment & Context	G	External systems and flow connections
Interfaces & Boundaries	B	Delineated inputs/outputs across system edges
System Behavior	T	Transformation of component states and flows
Lifecycle & History	H, Δt	Evolution and traceability over time
Emergence and Complexity	T, H, hierarchy	Outcomes of internal interactions and nested systems

This alignment enhances both theoretical rigor and modeling precision, complementing the SECM's conceptual focus with mathematical structure.

A General System Model for Systems Engineering

The general system model scuh as that provided by Mobus could provide scientific underpinning for:

Unified structural and behavioral modeling

Quantitative basis for feedback and emergence

Compatibility with systems modeling languages (e.g., SysML)

Support for lifecycle traceability and transformation

For example, in an engineered mobility system:

C: Subsystems (powertrain, sensors, chassis)

N: Wiring and data bus interconnections

G: Urban infrastructure, regulations, users

B: Interfaces such as GPS, brakes, communications

T: Acceleration, routing, braking logic

H: System logs, performance metrics

Δt: Millisecond-level telemetry samples

Implications for Systems Engineering Practice

By grounding SE concepts in a general systems science model, systems engineering would gain:

A formalized system context for MBSE

Improved capability to represent feedback, hierarchy, and emergence

Alignment with system science education and interdisciplinary fields

Every discipline has a set of underlying principles which fundamentally characterize it. Discipline knowledge and practice are either explicitly or implicitly derived from its principles. For example, one of the principles of physics is that the speed of light is constant. This specific principle has been validated countless times in practice and is broadly accepted as how the universe works. One common economic principle is that “Every choice has an opportunity cost”. (University of Minnesota n.d.) Another is the principle of supply, which states that “The quantity of a good supplied rises as the market price rises and falls as the price falls”. (Ehrbar 2007) Generally, disciplines do not have one authoritative complete set of principles. Different authors emphasize different aspects of a discipline in the principles they identify and explain. As fields mature, new principles emerge, and old principles may change. For example, Einstein’s Theory of Relativity revealed that the principles underlying Newtonian physics were not absolutely true. Yet, they are still immensely valuable most of the time.

Introduction

Systems engineering is a young discipline. The emergence of a set of systems engineering principles occurred over the past 30 years within the discipline. The development of these principles derives from many sources including heuristics Systems Engineering Heuristics (i.e., experience based), sociology, physical sciences, and mathematics. The INCOSE Systems Engineering Principles Action Team (SEPAT) reviewed various sources of systems principles and systems engineering principles identified in literature over this period. This article surveys this work and identifies a set of systems engineering principles based on this review.

Systems engineering principles are a form of guidance proposition which provide guidance in application of the systems engineering processes and a basis for the advancement of systems engineering. Systems engineering has many kinds of guidance propositions that can be classified by their sources, e.g. heuristics (derived from practical experience), conventions (derived from social agreements), values (derived from cultural perspectives), and models (based on theoretical mechanisms). Although these all support purposeful judgement or action in a context, they can vary greatly in scope, authority, and conferred capability. They can all be refined, and as they mature, they gain in their scope, authority, and capability, while the set becomes more compact. A key moment in their evolution occurs with gaining insight into why they work, at which point they become principles. Principles can have their origins associated in referring to them as "heuristic principles", "social principles", "cultural principles", and "scientific principles", although in practice it is usually sufficient to just refer to principles. Systems engineering principles are derived from principles of these various origins providing a diverse set of transcendent principles based on both practice and theory (Rousseau, Pennotti, & Brook 2022).

System principles differ from *systems engineering* principles differ in important ways (Watson 2018a). System principles address the behavior and properties of all kinds of systems, looking at the scientific basis for a system and characterizing this basis in a system context via specialized instances of a general set of system principles. SE

principles are a specialized and contextualized instantiation of systems principles that address the approach to the realization, use, and retirement of systems. SE principles build on systems principles that are general for all kinds of systems (Rousseau, 2018a) and for all kinds of human activity systems (Senge 1990, Calvo-Amodio & Rousseau 2019). Hence, system principles guide the definition and application of SE processes – a strong systems engineer must be the master of both system principles and SE principles.

A number of people have proposed SE underlying principles, in part by building on system principles. Perhaps because of its youth, a consensus among the community is still developing on which SE principles are most central. Yet, it is valuable to examine a number of proposed SE principles as they offer insight into what some of the best minds in the field think are fundamental to the discipline. In reviewing various published SE principles, a set of criteria emerged for valid SE principles. A principle:

- transcends a particular lifecycle model or phase
- transcends system types
- transcends a system context
- informs a world view on SE
- is not a "how to" statement
- is supported by literature or widely accepted by the community; i.e. has proven successful in practice across multiple organizations and multiple system types
- is focused, concise, and clearly worded

Thus, system type, the context in which the system is developed and operated, or a life cycle phase do not narrowly define systems engineering principles. Systems engineering principles transcend these system characteristics and inform a worldview of the discipline. Principles are not "how to" statements, which are embodied in the processes, but provide guidance in making decisions in applying the systems engineering processes. Principles should have a strong reference basis supported by literature, or widely accepted in practice (i.e. heuristic basis) (keeping in mind that this success must transcend the system characteristics mentioned above), or both. Principles are focused, concise, and clear in well-constructed principles statements.

Literature currently contains several good articles on system principles. These principles provide a basis for the functioning of a system and seek to group scientific axioms, laws, and principles into a set of system principles. The main themes seen in the literature on system principles include system governance, system theory axioms, and system pathologies with a focus on complex systems and system of systems. Complex System Governance provides a set of nine Metasystem functions "To provide control, communication, coordination, and integration of a complex system". These functions provide a basis from which to understand the functions of complex systems and how to manage their acquisition (i.e., governance). (Keating et al. 2017a) These Metasystem functions also extend to systems of systems engineering (Keating et al. 2017b).

Advances in system theory produced a set of unified propositions stated as seven axioms "From which all other propositions in systems theory may be induced". These seven axioms map to 30 scientific laws and principles (Adams et al. 2014). These axioms focus on the scientific basis of systems. Further work on these axioms provides an integration construct and a slightly different mapping to the underlying scientific laws and principles (Whitney et al. 2015). This work provides a strong integration and advancement in system theory, focusing on the principles behind the scientific basis of a system.

System science approaches also incorporate system theory leading to 10 concepts of systems theory and systems thinking (Sillitto 2014). These 10 concepts focus on system principles providing a definition of system characteristics. A further development in system sciences produced a list of 12 systems sciences principles that also focus on the characteristics of systems (Mobus and Kalton 2015). Rousseau formally derived a statement and derivation of three principles of systems (Rousseau 2018a). In addition, an architecture of systemology and typology of system principles provides a good classification of scientific principles spanning from system philosophy through system practice (Rousseau 2018b). This work led to a framework for understanding system science principles

(Rousseau 2018c).

Other early work included a set of seven system science principles exhibited by systems (Hitchins 1992). Organizational principles were also defined as a set of 11 principles dealing with how to work successfully within an organization (Senge 1990). Principles of Systems Thinking describes a set of 20 system thinking principles captured and integrated from a variety of sources.

System pathologies is another interesting approach to understand "Circumstances that act to limit system performance or lessen system viability (continued existence) and as such they reduce the likelihood of a system meeting performance expectations". These pathologies define diagnostics for understanding systems derived from a set of 45 system laws and principles. (Katina et al. 2016)

INCOSE compiled an early list of principles. This list consisted of 8 principles and 61 sub-principles (Defoe 1993). These principles were important considerations in practice for the success of system developments and ultimately became the bases for SE processes. These principles are reflective of how SE works in general. Following this work, several early versions of SE principles were compiled leading up to one of the first documented sets of SE processes. Project Performance International (Halligan 2019) has a set of SE principles that follow along the model set by Defoe providing considerations in the practice of SE, focusing on specific aspects within life cycle phases.

The Korean Council on Systems Engineering provided a survey article of 8 works on SE principles spanning the time from Defoe's principles through 2004 (Han 2004), including an early version of the PPI principles. These 8 works showed evolution of systems engineering principles from practice focused to more transcendent focused principles. In 1997, the INCOSE Systems Engineering Principles Working Group (no longer active) generated a set of 8 principles building from the work of Defoe over the course of several years of discussions. These principles were a mixture of process basis, modeling guidelines, and an early world view of the SE focus. The Institute of Electrical Engineers (IEE 2000), now part of the Institution of Engineering and Technology (IET), produced a set of 12 principles that also provided some basis for the systems engineering processes which are no longer extant. Lawrence Berkley National Laboratory (LNBL 2001) produced a set of systems engineering principles that embody the concepts captured by the INCOSE SE processes. In England, the Defence Engineering Group (DEG 2002) produced an SE Handbook with a brief set of principles guiding their processes and capturing some aspects of systems principles. Iowa State University is reported to have produced an SE Student Handbook containing a short list of SE heuristic phrases stated as principles. The KCOSE paper also referenced a lecture on SE principles from a course at the University of Southern California (USC) (Jackson, 2003). This lecture defined a principle as "A statement or generalization of a truth reflected in the systems engineering process", showing the focus on processes in the early SE principle development.

Some early forms of SE principles were also contained in textbooks on complex system development. (Adamsen II 2000) This set of principles assume a hierarchical system representation (complex systems have since shown to be more networks than hierarchies) and include statements on SE processes. Finally, system architecting books also included some early SE heuristics (Maier and Rechtin 2002). These heuristics read as sayings about some aspect of systems engineering practice.

The KCOSE Technical Board reviewed these 8 sources and voted that 8 of the principles from these sources as a set of SE principles, leading to an early form of transcendent principles consistent with the criteria defined above. These sources all show the early evolution stages of the SE principles as people looked at both formal and informal (i.e., course notes and student handbooks) sources to try to understand SE principles. The definition of the SE processes in works such as the INCOSE Systems Engineering Handbook fulfilled some of the objectives of these early works on SE principles and consolidated a lot of the work in this area. Recently, the need for more transcendent SE principles has been recognized, as a guide for applying the processes, which is the focus of current work by the SEPAT.

Over the last several years, a fresh look at the set of SE principles has emerged from the SEPAT. (Watson, et al. 2019) (INCOSE 2022) Its effort is based on SE postulates, principles, and hypotheses from the NASA Systems Engineering Research Consortium. This consortium followed the approach of Ludwig Boltzmann in defining his

postulates on gas distribution laws. Boltzmann's work is an early example of how to characterize the interactions of complex systems. A postulate is something assumed without proof to be true, real, or necessary. (Webster 1988) This led to the articulation of a set of postulates and hypotheses underlying SE which were expanded into a proposed set of SE principles. The underlying SE postulates and hypotheses matured over the course of 4 years (Watson et al. 2014; Watson et al. 2015; Watson & Farrington 2016). As the postulates matured so did the SE principles, providing more specifics in the application of SE, and the proof of a hypothesis becoming a principle (Watson et al. 2018; Watson 2018b). The final version of the principles is contained in a NASA Technical Publication on theory of systems engineering (Watson, et. al. 2020a) and a NASA Technical Publication on application of systems engineering approaches in practice. (Watson, et. al. 2020b)

The SEPAT developed 15 principles and 3 hypotheses, some expanded by subprinciples, described in INCOSE (2022). These were peer reviewed by several professional societies and represent the firsts steps towards consensus on systems engineering principles. These principles are:

1. SE in application is specific to stakeholder needs, solution space, resulting system solution(s), and context throughout the system life cycle.
2. SE has a holistic system view that includes the system elements and the interactions amongst themselves, the enabling systems, and the system environment.
3. SE influences and is influenced by internal and external resources, and political, economic, social, technological, environmental, and legal factors.
4. Both policy and law must be properly understood to not overly constrain or under-constrain the system implementation.
5. The real system is the perfect representation of the system. (models are only representations of real systems)
6. A focus of SE is a progressively deeper understanding of the interactions, sensitivities, and behaviors of the system, stakeholder needs, and its operational environment.
7. Systems Engineering addresses changing stakeholder needs a over the system life cycle.
8. SE addresses stakeholder needs, taking into consideration budget, schedule, and technical needs, along with other expectations and constraints.
9. SE decisions are made under uncertainty accounting for risk.
10. Decision quality depends on knowledge of the system, enabling system(s), and interoperating system(s) present in the decision-making process.
11. SE spans the entire system life cycle.
12. Complex systems are engineered by complex organizations.
13. SE integrates engineering and scientific disciplines in an effective manner.
14. SE is responsible for managing the discipline interactions within the organization.
15. SE is based on a middle range set of theories.

The SEPAT's recent articulation of SE principles elaborates on points made earlier by Defoe and emphasizes additional aspects of current SE practices, but there is nothing inconsistent between the two sets.

Principles of SE such as those proposed by Defoe and more recently articulated by the SEPAT are domain independent; i.e. they apply independent of the type of system being built, whether it is for transportation, healthcare, communication, finance, or any other business or technical domain. As they are applied, these principles can take more specialized forms, and/or can be complemented by other context-specific principles. Indeed, general SE principles such as these have been successfully applied in virtually every domain.

Systems Engineering Heuristics

-

Heuristics provide a way for an established profession to pass on its accumulated wisdom. This allows practitioners and others interested in how things are done to gain insights from what has been found to work well in the past and to apply the lessons learned. Heuristics will usually take the form of short expressions in natural language. These can be memorable phrases encapsulating rules of thumb, shortcuts or "words to the wise", giving general guidelines on professional conduct or rules, advice, or guidelines on how to act under specific circumstances. Common heuristics do not summarize all there is to know, yet they can act as useful entry points for learning more. This article overviews heuristics in general as well as some of those specifically supporting Systems Engineering practice.

Overview

Heuristics have always played an important part in the history of engineering and shaped its progress, especially before science developed to the point when it could also assist engineers. Systems Engineering is still at a stage at which there is no sufficiently reliable scientific basis for many of the systems being built, which has triggered a renewed interest in heuristics to fill the gap. This is especially true as the practice of Systems Engineering is extended to provide solutions to inherently complex, unbounded, ill-structured, or "wicked" problems (Churchman 1967).

Using heuristics does not guarantee success under all circumstances, but usefulness of a heuristic can be maximized if the known extent of its applicability is made clear. At their best, heuristics can act as aids to decision making, value judgements, and assessments.

Heuristics have the potential to be useful in a number of ways:

- reduce the amount of thinking (or computation) needed to make a good decision or a choice
- help in finding an acceptable solution to a problem
- identify the most important factors to focus on while addressing a complex problem
- improve the quality of decisions by drawing on best practices
- avoid repeating avoidable mistakes
- act as an entry point to wider knowledge of what has been found to work

Historical Background

Engineering first emerged as a series of skills acquired while transforming the ancient world, principally through buildings, cities, infrastructure, and machines of war. Since then, mankind has sought to codify the knowledge of "how to." Doing so allows each generation to learn from its predecessors, enabling more complex structures to be built with increasing confidence while avoiding repeated real-world failures. Setting out the aims for engineering in the 1st Century BCE, Vitruvius proposed a set of enduring principles: Strength, Utility and Beauty. He provided many examples of their applications to the fields of engineering of the time.

Vitruvius' writings were rediscovered in the Middle Ages, forming the basis of the twin professions of architecture and engineering. Early cathedral builders encapsulated their knowledge in a small number of rules of thumb, such as: "maintain a low centre of gravity," "put 80% of the mass in the pillars," and "observe empirical ratios between cross-section and span for cross-members.". Designs were conservative, with large margins, the boundaries of which were largely unknown. Numerous excellent structures resulted, many of which have endured to this day. When the design margins were exceeded, for example out of a desire to build higher and more impressive structures, a high price could be paid, with the collapse of a roof, a tower, or even a whole building. From such failures, new empirical rules emerged. Much of this took place before the science behind the strength of materials or building secure foundations was understood. Only in recent times has computer simulation revealed the contribution towards certain

failures played by dynamic effects, such as those of wind shear on tall structures.

Since then, engineering and applicable sciences have co-evolved: science providing the ability to predict and explain performance of engineered artifacts with greater assurance, and engineering developing new and more complex systems, requiring new scientific explanations and driving research agendas. In the modern era, complex and adaptive systems are being built which challenge conventional engineering sciences, with the builders turning to social and behavioral sciences, management sciences, and increasingly systems science to deal with some of the new forms of complexity involved and to guide the profession accordingly.

Koen (1985), went further, and argued that the whole of engineering was essentially heuristic in nature, since engineers could never know everything about whether what they built would meet their original intent, and how it would interact with an uncertain world. According to Koen, we must do what we can to tie these things down but make allowances for what we cannot know. He defined the engineering method as: *the strategy for causing the best change in poorly understood or uncertain situation within available resources*. He further claimed that heuristics are the only way of guiding our actions in these circumstances, and that the set of all heuristics agreed or used by a profession at any one time represents its 'state of the art'. He also put forward a number of universal heuristic principles for the conduct of engineering, covering areas such as: rules of thumb, factors of safety, engineers' attitude towards their work, managing risk and allocating resources. Although much of what Koen (a chemical engineer by profession) had to say remains relevant to systems engineers today, there is renewed optimism that scientific SE principles can be uncovered to underpin the discipline, just as they have done through the ages. (see Systems Engineering Principles)

Modern Interest

Renewed interest in the application of heuristics to the field of Systems Engineering stems from the seminal work of Rechtin and Maier (2009). Their book remains the best single repository of such knowledge, although efforts are now under way within INCOSE to update them for the 21st Century. Their motivation was to provide guidance for the emerging role of system architect as the person or team responsible for coordinating engineering effort towards devising solutions to complex problems and overseeing their implementation. Rechtin and Maier observed that it was in many cases better to apply "rules of thumb" than to attempt detailed analysis, especially when this was precluded by the number of variables involved, the complexity of the interactions between stakeholders, and the internal dynamics of system solutions and the organizations responsible for their realization.

An argument in favor of the wider use of heuristics was also made by Mervyn King (2016), who was Governor of the Bank of England during the 2008 global financial crash. Looking back, he said "it is better to be roughly right than precisely wrong": banks which observed the old bankers' rule of maintaining capital assets equal to 70% of their loan book survived, while those who relied on complex (and flawed) mathematical models of derivatives failed. He has become a powerful advocate for the use of heuristics alongside formal economics to allow bankers and others to deal with the uncertainties of global financial affairs in the modern interconnected world.

Further backing for the contemporary use of heuristics comes from Simon (1957), who coined the term "satisficing" for a situation in which people seek solutions, or accept choices or judgments, that are "good enough" for their purposes, regardless of whether they can be further optimized by precise analysis. He made the point that some heuristics were scientifically derived from experiment or systematic collection and analysis of real-world data, while others were just rules of thumb based on real-world observation or experience.

This idea has been further developed over a number of years by Gigerenzer and co-workers (for example, Gigerenzer and Selten (2001)), who have conducted research on heuristics which assist in making rapid decisions in areas of limited predictability, when probability theory is no longer helpful. They have developed a series of what they call "fast and frugal" rules of general applicability which have outperformed more conventional analysis in such areas as medical diagnosis and performance science (Raab and Gigerenzer 2015). The application to Systems Engineering has so far been little explored.

Practical Use

Experience of using heuristics suggests they should be memorable and can be most effective when phrased informally. The best examples are more than just literal expressions; they should resonate with the readers and suggest additional meaning, encouraging them to find out more about why and when to use them.

There is an underlying issue here: if you haven't experienced the situation for which the heuristic applies, it may mean little to you, and the inherent value may well be lost; but if you already have relevant experience, you may find it obvious. The use of heuristics is therefore linked to how we learn. In a world where experience is vital, but the number of opportunities to learn on the job is limited by the number of big projects one systems engineer works on in a lifetime, the learning process has to be accelerated. Heuristics can help here if linked to other knowledge sources and accessible at the right points in a career, as part of life-long learning.

A repository of heuristics can also act as a knowledge base in its own right, especially if other media, such as video clips or training materials, or even interactive media are added to encourage discussion and feedback. Such a repository might also link to other established knowledge sources or company websites. It can be organized to reflect accepted areas of practice or in a data base tagged with metadata to allow flexible retrieval. Maier and Rechtin (2009) suggested that a repository might also act as a "reading room," allowing users to move freely among associated subjects as if they were following their curiosity in a library or a bookshop. Such a repository could also allow users to assemble a set of heuristics most meaningful to them, relevant to their personal interest or professional sphere of activity.

A further possible use of heuristics was demonstrated by Beasley, et al (2014), who used a selection in a survey to uncover how key aspects of Systems Engineering were addressed within their organization. They asked their staff to mark the heuristics according to their importance to the business and whether they were observed in practice. Analysis of the answers allowed attention to be given to areas requiring improvement.

Broadly speaking, interest in heuristics now centers on their use in two main contexts: first, encapsulating engineering knowledge in an accessible form, where the practice is widely accepted and the underlying science understood; and second, overcoming the limitations of more analytical approaches, where the science is still of limited use. In either case, a good set of heuristics requires active maintenance to reflect the evolution of practice and our constantly developing understanding of what works best. A well-curated collection of heuristics allows practitioners to retain and represent the accumulated practical wisdom of the community of the Systems Engineering profession.

This article finishes with a few simple examples applicable to early stages, with some commentary to suggest their hidden meanings and where they might lead.

- ***Don't assume that the original statement of the problem is necessarily the best, or even the right one.*** The same point is repeated in many heuristics, such as: "The hidden assumptions are likely to be the most damaging," and "The customer may know what he wants, but not what he needs." All this has to be handled with tact and respect for the user, but experience shows that failure to reach mutual understanding early on is a fundamental cause of failure, and strong relationships forged in the course of doing such work can pay off when solving more difficult issues which might arise later on.
- ***In the early stages of a project, unknowns are a bigger issue than known problems.*** Sometimes what is being asked for is obscure, and the whole context of the systems engineering remit difficult to know, especially in areas of high uncertainty. The starting question may be less 'What are the Requirements for this?" and more "What's going on here?". (Kay and King 2020) Unpeeling the layers of meaning behind the second question may require methods drawn from systems thinking – looking for root causes, for example – and can take a project into unexpected areas. Again, soft skills such as empathy and intuition may be more important than those of conventional engineering.
- ***Model before build, wherever possible.*** This heuristic draws one in to the deeper question of the general use and limitation of models as a way that systems engineering tries to predict desirable and undesirable emergent system

properties before committing to build it. A related heuristic states "When you test a model of a system in the real world, you validate the model not the system," and a Theorem from System Science states "The only complete model of the system is the system itself." One heuristic leads to another, leading to reflection on how systems are built in the highly uncertain world of hyperconnected IT systems, where one might postulate that "The only complete model of the system in its environment is the system in its environment," which leads into using evolutionary lifecycles, rapid deployment of prototypes, agile life cycles, and so on. The original heuristic opens a door into 21st Century systems.

- ***Most of the serious mistakes are made early on.*** This heuristic summarizes much of what has just been said. Just to show that much what is believed now might have been known for some time, here is a quote from Plato: "The beginning is the most important part of the work." (Plato 375 BCE).

Finally a heuristic about heuristics – where they come from and what they are for – is taken from a fortune cookie and provides a summary: "The work will tell you how to do it." (Wilczek 2015) The serious point being made here – apart from showing that folk wisdom can have a part to play – is that the most important lessons about how to do Systems Engineering ultimately derive from the collective experience of the community of systems engineers as they undertake their profession. Even the science used to support heuristics must prove itself in practical situations.

This article introduces The Nature of Systems knowledge area (KA). Systems cannot be separated from their environment and human conceptions of system are contingent upon relations within specific (constrained) situations. Whilst the previous sections are concerned with the Introduction to System Fundamentals, or "The Engineering of Useful Artefacts" (Mobus, Kalton 2014); This section aims to illustrate the nature of systems, a compact description of essential themes relevant to a 'systems sciences' approach to this understanding, and to recognizing interdependencies between systems science and practices of systems engineering.

Introduction

This Knowledge Area (KA) introduces foundational perspectives on the nature of systems across disciplines, including natural, social, and engineered domains. It provides a conceptual bridge between systems science and systems engineering by clarifying essential systemic concepts such as identity, behavior, purpose, and value.

Where previous sections of the SEBoK focus on the engineering of useful artefacts, this KA explores the systemic qualities that underlie all types of systems, whether physical or conceptual, naturally occurring or human-made. It supports systems engineers in gaining a deeper understanding of how systems behave, evolve, and interact with their environments, and how this understanding can improve the design, implementation, and governance of complex engineered systems.

System World Views

While a broad spectrum of perspectives on concrete systems derives from practices of Systems Engineering (Sillitto, et al 2018) and other systems-cantered disciplines, the discipline of Systems Science seeks abstract, generalized, and universally applicable concepts, principles, and theories of systems. The overarching concept ‘system’ applies to any physical or conceptual subject of interest , including abstract domains of knowledge.

A system is a set of interrelated components. The components are variously linked to one another, and the system itself is connected to its surroundings. All systems have a boundary. In the case of designed or physical systems, the boundary is clear. In social and metaphysical systems, the boundary is typically more dynamic, less obvious, and more open to interpretation. In other words, observers are likely to perceive the boundary of a social or metaphysical system differently. According to Bogdanov (Bogdanov 1996), a system (or complex) is not simply a collection, aggregate (or vector) of components and their relationships. A system is a process, or continuous flux of independent granular processes, concatenated in self-triggering circles of build-up and degradation. Bogdanov's system cannot be separated from its environment, because it does not simply exist or interact with its environment: it is structurally coupled with its environment and thus evolves its own environment while co-evolving with it.

A common observation about systems is that they display properties which are not apparent from the properties of the components themselves. This is sometimes referred to as synergy, or as emergence.

While a system is often perceived as a structure, the unique properties come from the relations between the components within this structure. For example, trees provide shade from the sun and so can function as a refuge from heat. In the practice of systems engineering, a system is often identified with its functions. Designed systems exhibit one or more functions. Functions are useful properties in the context of a higher level system. The functions being an emergent property of the desired system's behaviour, and the system’s behaviour enabled by the structure of the system.

Systems can be both 'physical' and / or 'conceptual' things. Conceptual things, mental processes, often correlate with physical causes (eg, events observed in brains) and may be considered to 'constitute' a separate class of relational processes. If 'conceptual' things can be grounded in relational processes correlated with physical causes, it stands to reason that communicating meaningfully about physical causes at various spatial and temporal scales provides a theoretical basis for including conceptual and physical things in the domain of 'concrete' systems.

In this narrow sense it may be said that all subjects of interest take part in a 'unitary' system of 'concrete' (physical) nature. That is, as an irreducible physical unity, the universe is composed of conceptual and physical things existing in interlocking and subsuming processes of interrelation that may be described in subjectively relatable terms, in other words, 'understood'.

This 'systemness' (existing understandably in relational processes) is a general characteristic of all things. System Science provides useful frames of reference for meaningful approaches to both realms generally (eg, physical and social).

Definitions and Problems of terminology

In this overview article we recognize the (apparent) huge body of literature (a google scholar search on "nature of systems" returns 13,000 results) on the nature of systems. While a few basic definitions of systems (Sillitto, et al. 2018) are widely accepted in practice, significant differences in specialized usage exist.

Thus, here we try to use commonly understood terms meaningful to both both practitioners and scientists. While potentially useful to consider this diversity in terms of a more broadly organized taxonomy, it's helpful to appreciate that terminology is unlikely to be permanently 'fixed' or fully normalized; this contingent relation with human expression is a feature of the universe and dynamic interactions within it.

The dual nature of such contingency is notably paradoxical. On one hand, incommensurate terminology can present problems. On the other: opportunity. Together, in the open-ended relation between 'problem' and 'opportunity',

interesting things can occur.

The available knowledge about systems is very rich indeed but it is yet chaotic (the system of system knowledge often yields more questions than answers) and the domain of system science relates variously with many knowledge domains (specializations) in the broader culture. One of the goals of system science, therefore, is to purposively help reconcile such 'geographical' concerns - literally and figuratively. This leads to validating questions of valuation and realization for systems knowledge and systems science pursuits.

Value of systems knowledge

The nature of systems, as one of the most powerful and widely used paradigmatic conceptions is a common thread across human existence. Generally, systems in the universe do not embody human agency - humans and system scientists do. The validation, legitimation, and valuation of systems knowledge generally occurs in its relation between human situations. More specifically, system science in the service of systems engineering (or vice versa) recognizes and is capable of anticipating and delivering value for system stakeholders - who are typically situated in systems of other derivation (cultures that do not necessarily share a common system language).

Systems science (as an activity system) adds value by organizing and tailoring concepts, theories, principles and assets which render useful expressions of fact, concern, effect or degree pertaining to forms, functions, and fitness of systems in the landscape of systems competencies.

These patterns of expression help stakeholders anticipate complex dynamic situations and compose descriptions and sequences of action (eg, plans) in multiple relatable - and reliable - ways. System scientists must communicate with a range of stakeholders in order for systems to be engineered to operate predictably well. In turn, stakeholders must be conversant in the 'local' language(s) of their systemic interest; often this takes priority and the value of system science is in expressing knowledge in terms stakeholders understand rather than the other way around.

Clearly, the nature of systems can be elusive and pursuit of systems knowledge a great challenge. Future articles in this KA are continually being developed to complement (and also improve upon) existing articles. The concepts in the titles of the articles can always be improved upon but the essence of the content should be consistent with this compact description, as it captures foundational themes in our understanding of the relation between human minds and the universe we are present to.

A Set of Systems Concerns

One of the aims of this section is to illustrate the wide array of concerns in systems science literature. Looking across the literature, there is a a notable variety of useful categorical mappings and taxonomies. Here we introduce ten representative concerns of systems science; the list is intended to be illustrative rather than definitive.

1. Identity: Bounded networks of relations among simplified elements constitute a nominal and semantically meaningful unit, pragmatically speaking. This 'systemness' is a general characteristic of all things and can often be represented (expressed) as a non-random (informative) network of symbols.
2. Processes: layers, levels, and dimensions of dynamically *changing structure and function.*
3. Networks of relations between elements: connectivity, structure, and holistic properties such as resilience, criticality, efficiency.
4. Dynamics on multiple time scales: states and sequences of change such as growth, collapse, cycling, pattern-formation, criticality.
5. Complexity : variability in number of elements and dimensions of element relations including additivity, connectivity, and inter-adaptability (contingency, dependency).
6. Evolution: progression of qualitative, quantitative, and/or semantic change over time.
7. Information: matter and energy 'encoded' within network(s) of relation or exchange between senders and receivers.

8. Governance: modes of mutual regulation and adaptation between elements, typically involving synergetic co-operation or competitive interference.
9. Contingency: degrees of freedom within a network of constraints which the system is subject to.
10. Methods of interaction. Profoundly, every system has a kind of signature; a unique way of showing up to human cognition, through which it reveals or exchanges information and yields knowledge about its state and identity; Practically, this involves (human) stakeholders and their respective processes of attention. In regard to system science and engineering - attention to specific exchanges of energies *through* bounded interfaces (eg, scientific instrumentation; sensing/measuring systems), rather than narrowing-in on surface experience *of* limitations and boundaries. In other words, system science is a process of open ended learning.

Gaining a 'feel' for systems

Systems are an ordinary occurrence; we are immersed in systems. It is a challenge, however, to discover the unity in the immense diversity of ways systems manifest in experience. Considering the far-ranging Body of Knowledge underlying Systems Engineering, 'natural kinds of value' are foundational. All systems exist in our natural context and can be experienced as values. These values relate to utilities stemming from systems knowledge and its application, ranging from guiding personal day-to-day actions to addressing global challenges.

Within the structure of this section of the SEBOK we shall be giving presentation to interwoven concepts of Togetherness, Character/Behaviour, Cycles, Purpose, Value, and Learning/Experience (Rousseau, et al. 2018) as a way of providing a cognitive system of values, and a holistic perspective on situated systems, systems in practice, that can deeply align theoretical and practical efficiencies of the systems engineering discipline.

The form of things: Togetherness provides a framework for collaborative and integrated operations, emphasizing the indispensability of harmonious interrelations at the heart of successful systems. Behaviour informs the adaptable and responsive dynamics that are essential for the resilience and robustness of engineered entities.

The function of things: Cycles highlight the recent and iterative nature of systems, underscoring the importance of feedback mechanisms in persistent operation and effectiveness. Purpose anchors systems with a definitive direction and intentionality, centering on outcomes that deliver meaningful impact.

The fitness of things: Value signifies the critical evaluation of a system's effects, ensuring that resource utilization and stakeholder interests are aligned. Experience centers the human-centric aspects of system concepts, definition, realization and operation, ensuring human appreciation, influence, and subsidiarity.

These six intertwined concepts provide a conceptual scaffolding upon which systems engineering may appreciate the nature of systems when fulfilling the requirements of Form, Fit and Function.

In practice, these general concepts and the theoretical models that build upon them translate through to the application of specific assets such as that utilized in our lifecycle management processes as discussed in the article in this KA.

Applications engendered by these assets play out in the creation and modification of systems artefacts and complex entities involving living systems. Here, the natural kinds of value are further actualized through the actions of embedded computational networks (themselves products of evolutionary refinement); continuous regeneration of self-sufficient organic systems, promotion of sustainable resource cycles, alignment of system functionalities within overarching frameworks of values, elevation of stakeholder value, and enhancement of user interaction with technology.

In general, guidance offered for practical use of systems knowledge spans various dimensions of human activity. It helps direct rationalizations taking place in personal decision-making through to the strategic considerations necessary for addressing complex global issues. By operationalizing the six concepts at every level—from nanotechnology to large-scale infrastructure, systems engineering integrates natural kinds of value with a complex of systems critical to technical, social and natural systems safety and well-being.

In summary, the six system concepts serve as theoretical keystones that, together with methods and applications (facilitated by relevant assets at hand), aim to deliver natural kinds of value at every scale of human enterprise. Integrating these theories, methods, and applications fosters an approach to systems engineering that thrives on adding net intrinsic value. Through such an approach engineered systems transcend mere functionality, endowing them with qualities that support and enrich the human experience in its broadest context.

This is by no means a complete landscape of systems concepts, rather it may help to scaffold a useful entry point into the diverse inspirations and instrumental concepts for systems engineering.

Value of a Systems Science Foundation for Systems Engineers

The urgency of understanding common foundations of systems for practicing SE's can be summarized in three points:

1. Civilization depends upon highly evolved physical and conceptual systems and recent evidence from planetary science https://www.ipcc.ch/reports [1] indicates that planetary support systems are changing significantly and relatively quickly. Civilization is an ongoing co-evolutionary System of Systems with Humankinds' Planetary Support system, and recent evidence indicates that the rate of change is increasing; Civilization depends upon highly evolved planetary systems and recent evidence from planetary science (limits to growth update) indicates that these are changing significantly and relatively quickly;
2. The practice of Systems Engineering is embedded in and co-evolves with the proliferation of socio-technical systems that constitute modern civilization;
3. Designing, integrating, and evolving socio-technical systems becomes more complex and challenging as new technical specialists become involved in Systems Engineering processes. For instance, adding environmental, economic, social, and governance specialties in-creases workload for the key Systems Engineering role of System Integrator and Communicator.

The considerable value of Systems Science could be demonstrated in helping address these key Systems Engineering challenges by:

1. Framing common-view characteristics of all systems relevant to a given System of Interest and the environment of interacting System of Systems 's so that appropriate tools, techniques, and processes can be employed and/or developed for efficiently working across the system design and development community;
2. Facilitating effective cooperation between diverse technical specialists bringing unique concepts, models, and vocabularies and promoting inclusive equity for enhanced project/program/system success: it's essential for all stakeholders to appreciate their specific situational role(s) in systems of interest co-evolution with interacting systems of systems, to more effectively engage in realizing critical shared objectives.

-

Introduction

Engineered systems are purposeful, human-defined systems created to achieve specific objectives. They are central to systems engineering practice and include products, services, enterprises, and systems of systems (SoS). These systems must be conceived, developed, integrated, and sustained across complex life cycles, often within dynamic and unpredictable environments.

This article complements related entries on **Natural Systems** and **Socio-Technical Systems**. Together, these perspectives provide a more holistic understanding of system types encountered in practice.

Importantly, although engineered systems are designed and assembled by humans (and increasingly with AI assistance), they are **not separate from nature**. They are embedded within the physical world, governed by natural laws, and constrained by the same energy, material, and information flows that structure all natural systems. This duality, that engineered systems are both *products of intentional design* and *participants in broader natural systems,* is a key theme throughout this Knowledge Area.

Engineered Systems as Natural Phenomena

Engineered systems are often conceptualized as distinct from natural systems. However, systems science reminds us that they are **subsets of natural systems**:

- They are composed of physical materials, constrained by the same thermodynamic and ecological principles that govern all natural processes.
- Their behaviours emerge from feedback loops, control mechanisms, and relational dynamics consistent with other systems in the universe.
- They generate effects, intended or not, that interact with ecosystems, societies, and planetary systems.

The design of engineered systems therefore requires not only technical ingenuity, but also **an appreciation for their ecological and systemic context**. Engineering that is blind to natural laws or environmental coupling risks unsustainable or unstable outcomes. Conversely, engineered systems that align with natural cycles, resilience principles, and ecological limits can enable regenerative and adaptive capabilities at scale.

This perspective resonates with foundational concepts explored in the articles on:

- **Cycles and Phases –** highlighting lifecycle rhythms, renewal, and iteration
- **Value and Qualities –** emphasizing stakeholder and systemic outcomes beyond function
- **Experience and Consciousness –** recognizing human-system interactions and feedback
- **Natural Systems –** describing self-organizing systems as constraints and inspirations

System Classification

Engineered systems are one class within broader taxonomies of systems developed in systems science. Several influential frameworks include:

- **Boulding (1956):** A hierarchical classification ranging from structures and organisms to social and transcendental systems.
- **Checkland (1999):** Five categories: natural systems, designed physical systems, designed abstract systems, human activity systems, and transcendental systems.
- **Magee and de Weck (2004):** A functional classification of systems by process (transform, transport, store, exchange, or control) and by the entity on which they operate (matter, energy, information, or value).

Engineered systems are typically situated in the class of **designed physical and abstract systems**, where intentional function, lifecycle logic, and stakeholder goals are dominant, but still operating within natural constraints..

Types of Engineered System

Engineered systems can be grouped into four general contexts that are commonly recognized in systems engineering practice: **product systems, service systems, enterprise systems,** and **systems of systems (SoS)**. Each represents a possible *system of interest (SoI)* within a life cycle.

Figure 1 illustrates these contexts. A product may exist as a technology-focused system, integrated into a service; services are delivered and sustained by enterprises; and in many cases, systems are combined to form larger systems of systems

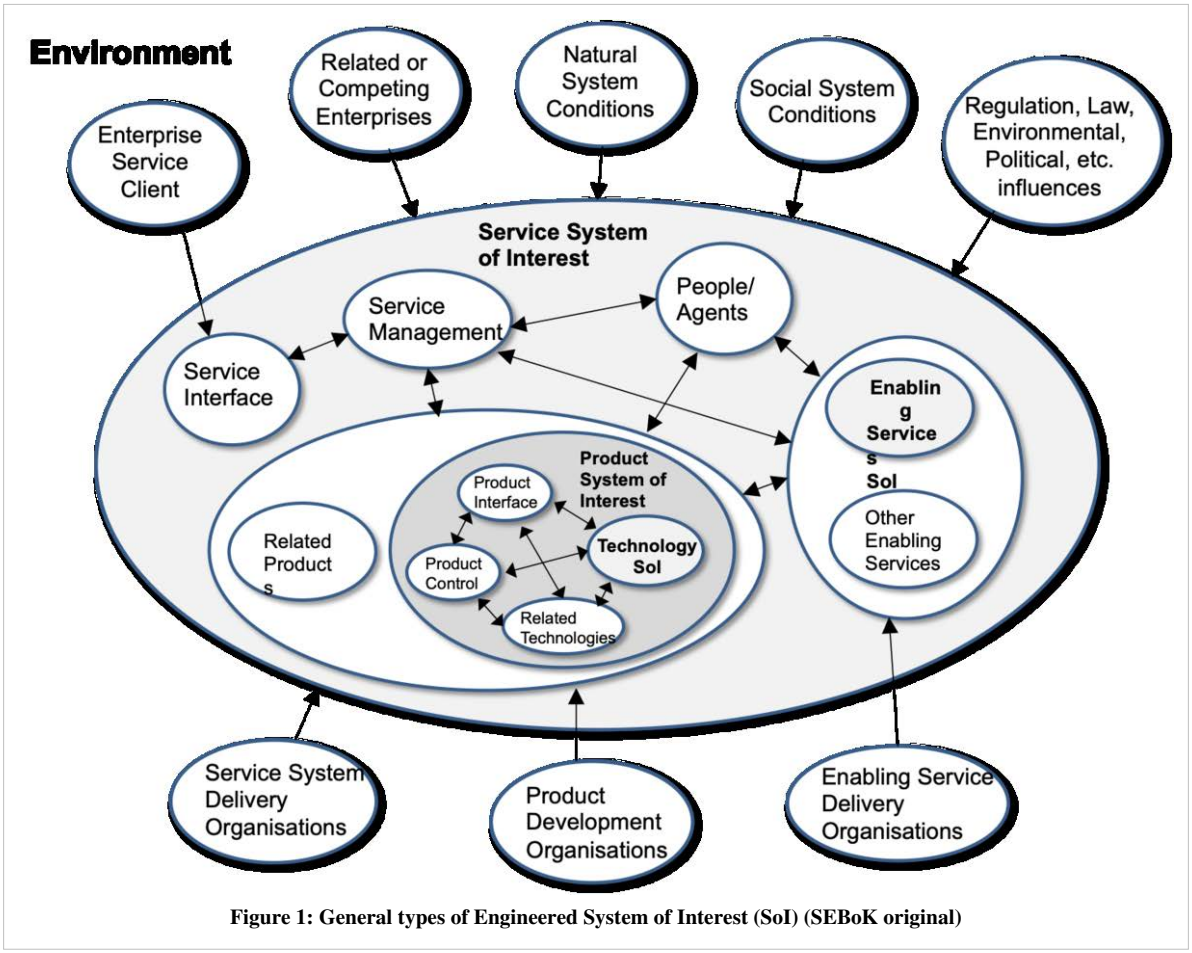

Figure 1: General types of Engineered System of Interest (SoI) (SEBoK original)

Products and Product Systems

A **product system** is an engineered system focused on the creation and delivery of tangible or intangible products, such as hardware, software, or information artifacts. The life cycle of a product system typically includes design, production, operation, sustainment, and eventual retirement.

Products do not exist in isolation: they interact with people (operators, maintainers, producers) and are deployed within service systems that deliver capabilities to an enterprise or society. Effective product system engineering therefore requires attention to both the product itself and its wider context.

Services and Service Systems

A **service system** is an engineered system that delivers outcomes or benefits to users. Services are processes or performances co-created with clients or stakeholders. Examples include transportation, healthcare, communications, and information technology services.

Service systems are often information-intensive and software-defined. They may involve combinations of products, people, and supporting infrastructure, integrated close to the point of use. Systems engineers address both the design of the service and the management of its delivery, ensuring performance, quality, and adaptability over time.

Enterprise Systems

An **enterprise system** is a purposeful network of people, processes, organizations, and technologies that interact to achieve shared goals. Enterprises are unique in that they are constantly evolving, rarely have fixed requirements, and typically balance multiple objectives such as customer satisfaction, stakeholder value, and long-term sustainability.

Systems engineering supports enterprises through **enterprise architecture** and related modeling approaches, which describe current capabilities and plan for future ones. These tools allow enterprises to align their strategy with the product and service systems that support their operations.

Systems of Systems

A **system of systems (SoS)** is an arrangement of independent systems that retain operational and managerial autonomy but are integrated to provide new capabilities. Examples include national defense networks, air traffic management systems, and smart cities.

SoS engineering involves unique challenges, including governance, interoperability, and lifecycle coordination across independently managed systems. As integration technologies become more common, SoS considerations are increasingly central to modern systems engineering practice.

Applying Engineered System Contexts

Real-world engineering efforts often span multiple system types. For example:

- A satellite product is operated within a telecommunications service,
- Managed by an aerospace enterprise,
- And integrated into a defence SoS.

Systems engineers must therefore define the **system of interest (SoI)** within a given project or activity, while remaining aware that it exists within broader systems-of-systems and natural environments.

This awareness includes:

- Defining clear boundaries and interfaces
- Understanding enabling and interacting systems
- Recognizing cycles of feedback and adaptation
- Designing with foresight into ecological and social impacts

The **article on Identity and Togetherness** provides further perspective on boundary definition and system coherence across contexts.

Interfacing with Natural and Socio-Technical Systems

Engineered systems:

- **Depend on natural systems** for materials, energy, and stability (see *Natural Systems: Principles and Attributes*)
- **Shape and are shaped by social systems**, including regulation, usage, and cultural norms (see *Value and the Quality of Systems*)
- **Must evolve to fit within dynamic environmental conditions**, respecting planetary boundaries and long-term resilience requirements

As engineered systems become more complex and intelligent, **they increasingly resemble natural systems,** exhibiting self-organization, learning, and emergent behaviour. This convergence suggests the need for system engineers to understand:

- The **limits and affordances of physical law**
- The **patterns of natural system organization**
- The **ethical responsibilities of system design** in relation to society and ecology

Summary

Engineered systems are intentional, human-defined systems developed to fulfill specific functions. Yet, they are also deeply **natural,** built within and governed by the physical world, and inevitably connected to broader ecological and social systems.

By situating engineered systems within the wider landscape of systems types, this article supports a more integrated and reflective approach to engineering practice. It complements other articles in this Knowledge Area that explore the shared principles, behaviours, and values that cut across both natural and artificial systems.

Understanding this interconnection is essential for designing **systems that are not only effective, but also sustainable, adaptable, and ethically coherent** in the complex systems landscape of the 21st century.

Introduction

Natural systems are **self-organizing, dynamic systems** that occur in nature without direct human intervention. They consist of interacting physical, chemical, biological, and ecological components that have existed and evolved over billions of years, and operate according to the laws of physics and natural processes (i.e. evolution, natural selection). Natural systems typically exhibit feedback loops, energy flows, material and temporal cycles, and can be viewed as open systems governed by boundary conditions and conservation laws (e.g., mass, energy, momentum). Inputs such as solar energy or precipitation drive outputs such as runoff, heat, and carbon flux, creating continuous cycles that sustain life and ecological balance.(Capra & Luisi, 2014; Morowitz, 2002).

Understanding natural systems is essential for systems engineers because it:

- Reveals recurring **systemic principles** that govern stability, resilience, adaptation, and transformation;
- Provides **constraints** that must be respected in engineered solutions;
- Offers **models and metaphors** that can inspire innovation, sustainability, and long-term viability;
- Helps situate engineering within the broader fabric of planetary systems and ecological interdependence (Mobus & Kalton, 2015).

What Makes a System "Natural"?

Natural systems differ from engineered systems not because they are simpler or less functional, but because their **organization arises from internal and environmental interactions**, not from top-down design (Jantsch, 1980; Bunge, 1979). Key characteristics of natural systems include:

- **Self-organization**: Structure and function emerge without centralized control
- **Openness**: Exchange of energy, matter, and information with the environment
- **Multi-scale dynamics**: Nested spatial and temporal scales of operation
- **Evolutionary adaptation**: Variation, feedback, and selection processes
- **Constraint-driven behaviour**: Shaped by physical and thermodynamic laws (Odum, 1983)

These systems may be living (organisms, ecosystems), non-living (climate, plate tectonics), or complex hybrids (e.g., microbiome–host systems).

Natural Systems in the Engineering Context

Natural systems are deeply entangled with engineered systems in three primary ways:

1. Constraint

Engineered systems must respect the physical and ecological limits of the environment, such as energy flows, entropy, material cycles, and climate stability (Rockström et al., 2009).

2. Context

Natural systems form the surrounding conditions into which engineered systems are embedded. This includes local ecosystems, weather, geological features, and socio-ecological dynamics (Folke et al., 2010).

3. Inspiration

Natural systems offer design patterns and strategies, such as modularity, feedback regulation, and redundancy, that can be abstracted and applied to engineered systems (Benyus, 1997; Vincent et al., 2006).

This triad (constraint, context, inspiration) aligns with the broader themes in this Knowledge Area, particularly:

- *Cycles and Phases* – natural systems are inherently cyclic (e.g., water cycle, nutrient flow)
- *Purpose and Capabilities* – while not consciously goal-seeking, natural systems exhibit coherent and evolving functions
- *Value and Qualities* – natural systems provide ecosystem services and intrinsic values increasingly recognized in engineering decisions

Properties of Natural Systems

Natural systems exhibit a range of properties, some of which are shared with engineered systems, while others are distinctive.

Shared System Properties	Distinctive Natural Properties	Engineering Relevance
Resilience: Return to stable state after disturbance	**Growth**: Increase in capacity and structure over time	Informs scalable and sustainable design
Robustness: Maintain function across variable conditions	**Regenerability**: Restore function after degradation	Inspires recovery and renewal strategies
Adaptability: Reconfigure to meet new conditions	**Anti-fragility**: Improve through exposure to stress	Basis for learning systems, evolutionary computation
Sustainability: Persist within changing environments	**Flourishing**: Support reciprocal relationships	Guides circular economy, cooperative architectures

These properties arise from systems' embeddedness in feedback-rich, evolving environments (Meadows, 2008; Gunderson & Holling, 2002). Systems engineers can draw on these traits to inform lifecycle design, risk management, and adaptive response.

Examples Across Disciplines

Engineering Domain	Relevant Natural Systems
Civil & Environmental	Watersheds, floodplains, geochemical cycles
Aerospace & Mechanical	Atmospheric dynamics, thermodynamics
Electrical & Bioengineering	Neural networks, electrochemical signaling
Systems Engineering	Ecosystem modeling, food web resilience, system dynamics

These examples illustrate how natural systems can serve as **reference architectures**, **benchmarks**, or **integrated constraints** in engineering thinking.

Implications for Systems Engineering

Systems engineers increasingly work in domains where **natural and engineered systems intersect,** from sustainable infrastructure to adaptive software agents embedded in biological environments.

Understanding natural systems supports:

- **Transdisciplinary modeling** (e.g., integrating ecological and technical models)
- **Systems-of-systems planning** under conditions of uncertainty and change
- **Resilient and regenerative design strategies**
- **Ethical awareness** of systemic externalities and responsibilities

As engineering challenges become increasingly complex and planetary in scope, the **principles of natural systems provide a guide** for designing with humility, foresight, and systemic alignment.

Summary

Natural systems are not external to engineering, they are its context, constraint, and sometimes its inspiration. By learning from natural systems, engineers can design more adaptive, sustainable, and resilient systems that contribute positively to the complex web of life.

This article supports further exploration in the KA through:

Natural Systems: Principles and Attributes

Natural systems are the most enduring systems in the known universe. Shaped by billions of years of evolution, they exhibit systemic patterns that support resilience, adaptability, and sustainability. While engineered systems are often designed with a focus on efficiency and function, natural systems offer a deeper repertoire of systemic principles and attributes that are relevant to modern systems engineering, especially in the face of global complexity, planetary limits, and socio-technical interdependence.

This article explores those principles and attributes, drawing on foundational work from systems science, including **systems processes and isomorphies** (Troncale 2014), and **visualizing dynamic patterns** (Rasmussen 2024). By studying natural systems, systems engineers can draw inspiration and guidance for designing systems that are not only technically effective but also ecologically integrated and future-fit.

Principles, Attributes, and Engineering Implications

The following table presents core **principles of natural systems**, the **characteristic attributes** they give rise to, and **implications for systems engineering practice**. These principles emerge through long-term interactions within and across multiple scales, yielding patterns of systemic health.

Principle of Natural Systems	Characteristic Attribute	Systems Engineering Implication
Self-Organization – ordered patterns and functions emerge without centralized control	**Emergent complexity**	**Supports decentralized architectures (e.g., swarm robotics, adaptive SoS) and reduces reliance on single points of failure**
Adaptation through Feedback – positive and negative feedback regulate behavior	**Dynamic responsiveness**	**Informs control theory, adaptive algorithms, and real-time monitoring in cyber-physical systems**
Decentralization and Modularity – distributed control and modular subsystems	**Scalability & autonomy**	**Guides modular open system architectures (MOSA), enabling independent upgrades and resilience**
Resource Efficiency – optimal use of materials and energy in closed loops	**Sustainability, ecosystem services & circularity**	**Encourages lifecycle efficiency, closed-loop supply chains, and energy/material minimization**
Redundancy and Diversity – multiple pathways and variation buffer against disruption	**Robustness & fault tolerance**	**Informs fault-tolerant design, diversity in redundancy strategies, and resilience engineering**
Hierarchical Organization – nested levels of structure and function	**Multi-scale integration**	**Supports hierarchical system decomposition and layered architectures (e.g., C4ISR, enterprise systems)**
Evolutionary Iteration – improvement through variation, selection, and retention	**Iterative improvement & adaptability**	**Reinforces agile development, evolutionary algorithms, and continuous verification/validation**
Co-evolution and Symbiosis – systems adapt in relation to one another	**Interoperability & cooperation between ecosystem level interfaces**	**Informs SoS engineering, ecosystem integration, and collaborative architectures**
Anti-Fragility – *c*apacity to recover or improve through stress	**Resilience, enhancements in capability**	**Provides design principles for contested or high-risk environments, emphasizing system responsiveness, recovery and learning**
Cyclical Temporality – system behaviors often occur in recurrent patterns or cycles	**Dynamic responsiveness to repeating events across system elements and hierarchies**	**System scheduling, buffering, and pacing in response to its environment**

These principles are observed in ecosystems, biological processes, and geophysical phenomena. Collectively, they create systems capable of thriving under uncertainty, maintaining coherence across scales, and adapting to long-term environmental change.

Toward a Nature-Informed Paradigm for Systems Engineering

Natural systems offer both **conceptual insight** and **practical reference models** for engineering. They exemplify the integration of **form**, **function**, and **fitness,** a triad that aligns with the **Fit–Form–Function** lens applied across this SEBoK knowledge area. Natural systems do not aim for single-purpose optimization, but instead balance multiple system goals (e.g., stability, diversity, and renewal).

Adopting a nature-informed perspective allows systems engineers to:

- Design for **resilience**, not just reliability
- Develop systems that **coexist** with natural ecosystems
- Build **adaptive capacity** into complex socio-technical infrastructures
- Leverage principles such as **circularity** and **interconnectedness** to mitigate unintended consequences

Reference Models from Nature

Natural systems can be used as reference models across different engineering challenges:

- **Ecosystems** (e.g., forests, coral reefs): inspire distributed regulation, symbiosis, and multi-species cooperation
- **Biological processes** (e.g., photosynthesis, decomposition): illustrate closed-loop material flows and energy efficiency
- **Geophysical systems** (e.g., plate tectonics, erosion): show long-term adaptation, thresholds, and transformation
- **Atmospheric/oceanic dynamics** (e.g., jet streams, ocean currents): model distributed control, feedback loops, and buffering across vast scales

These models are particularly useful for **biomimicry**, **systems-of-systems design**, and **regenerative infrastructure**. They also reinforce the importance of **temporal design,** a theme central to both Troncale's cyclical isomorphies and Rasmussen's visualization of systemic patterns.

Design Heuristics Inspired by Nature

Systems engineers can draw upon the following heuristics informed by natural systems:

- **Design for redundancy with variation**, not just replication
- **Foster self-regulation** through feedback and monitoring
- **Embrace partial control**, allowing room for adaptation
- **Optimize for relationships**, not just parts
- **Co-evolve systems with their environments**
- **Respect planetary boundaries,** designing within ecological constraints

Implications for Problem-Solving, Design, and System Interactivity

- Modeling: bridging reference models to design and production models using analogies, particularly at functional levels
- Biomimicry: Innovative solutions that emulate nature's patterns for sustaining life.
- Systems Thinking: Holistic understanding of complex problems, recognizing dependencies and connectivity.
- Circular Economy: Value production systems that emulate natural cycles and functional relationships to help manage waste, promote reuse, and circulate materials and energy.
- Resilient Infrastructure: Embedding principles such as adaptability and self-organization can contribute to infrastructure responsiveness, reusability, and multi-functionality.

Relationship to Other Articles in the Knowledge Area

This article complements:

- **Natural Systems** (definition and scope)
- **Identity and Togetherness of Systems** (distinction, boundary, binding and wholeness)
- **Behaviour and Dynamics of Systems** (response patterns and change processes)
- **Cycles and the Phases of Systems** (temporal system states and changes)
- **Purpose and the Capability of Systems** (teleology and emergent function)
- **Value and the Quality of Systems** (systemic contributions to life and flourishing)
- **Consciousness and the Experience of Systems** (sentience, awareness, and information exchange)

Together, these articles scaffold a **unified systems view** integrating insights from **natural, engineered, and socio-technical domains**.

This article reflects established knowledge from systems science and systems engineering, organized and collated for the SEBoK. Drafting support was provided by OpenAI’s ChatGPT, with all content reviewed and finalized by the author, who retains full responsibility.

Introduction

Natural systems represent the most time-tested systems on Earth, shaped by billions of years of interaction, adaptation, and co-evolution across scales. These systems have persisted and transformed under conditions of uncertainty, constraint, and change. Their enduring success provides a foundational knowledge base for understanding systemic viability, resilience, and integration.

This article presents the **value proposition** for bringing natural systems perspectives into systems engineering. It outlines practical and strategic reasons why nature’s principles, structures, and patterns are relevant to the future of systems thinking and engineering practice, especially as we confront planetary-scale complexity and cascading systemic risks

By studying and abstracting strategies from natural systems, engineers can expand the solution space across domains such as structure, function, behavior, interfaces, and process dynamics. This can improve system performance and reliability, reduce risk, and increase efficiency in engineering processes (e.g., Benyus 1997; Mobus 2022).

Why Natural Systems Matter to Systems Engineering

Systems engineering has historically focused on the purposeful design of human-made systems to meet specified objectives. However, engineered systems increasingly operate within dynamic, interconnected environments that resemble the complex behaviour of natural systems. These contexts, ranging from cyber-physical infrastructure to social-ecological systems, demand design practices capable of dealing with:

- Multi-scale feedback and cascading effects
- Long-term resilience and regenerative capability
- Evolving stakeholder needs and boundary conditions
- Integration with planetary systems and natural limits

Natural systems provide:

- **Proven patterns of systemic health**, such as resilience, redundancy, adaptability, and regeneration
- **Functional strategies shaped by evolutionary constraint and selection**, offering robust solutions under real-world pressures
- **Conceptual bridges** that align science, engineering, sustainability, and policy
- **A reference architecture for systems of systems**, grounded in observed performance across temporal and spatial scales. Applying natural principles to engineered systems has already led to advances in areas such as materials science, functional capabilities, and system architectures. Examples include the lightweight strength of bone inspiring aerospace structures, neural processes informing artificial intelligence and control systems, and ecological resilience informing redundancy and diversity in system-of-systems architectures. In practice, engineers can learn from natural strategies to optimize system attributes, supporting performance criteria such as:
- Size-weight-power-function optimization
- Sensing and perception accuracy
- Cognitive adaptation and decision-making
- Resilience and anti-fragility under stress

Recognizing natural systems as both **context and inspiration** encourages systems engineers to move from isolated optimization to integrated co-evolution within the broader Earth system.

Functional and Strategic Value of Natural Systems Thinking

Domain	Value Contribution
Design Innovation	Biological and ecological dynamics inspire novel control architectures, scalable morphologies, and multifunctional materials (e.g., swarm robotics, self-healing surfaces)
Performance Optimization	Natural models inform optimization strategies for power-to-weight ratios, feedback timing, and multi-objective trade-offs (e.g., vascular flow, neural signal propagation)
Resilience and Robustness	Nature achieves systemic resilience through diversity, redundancy, and dynamic feedback, offering key heuristics for SoS and infrastructure design
Lifecycle Adaptability	Iterative change through variation, selection, and retention mirrors agile development, adaptive control, and evolutionary algorithmic approaches
Societal and Ecosystem Integration	Nature-based design supports circular economy, ecosystem services modeling, and integrated planning across human–environment interfaces

These insights can be applied not only at the product or project level, but across enterprise transformation, infrastructure resilience, and planetary stewardship.

Established Contributions from Natural Systems to Engineering Practice

Systems engineering has already begun to draw on nature-derived ideas in domains such as:

- **Neural networks and cognition-inspired architectures**
- **Bio-inspired materials**, such as lotus-effect surfaces and bone-mimicking composites
- **Distributed sensing and regulatory feedback**, modelled on biological networks
- **Ecological resilience frameworks**, applied to infrastructure planning and disaster response
- **Circular resource systems**, echoing nutrient cycling and metabolic closure
- **Holarchic decomposition**, reflecting the nested nature of ecosystems and organisms (see *Holarchy and Fit–Form–Function*)

Key contributors to this convergence include:

- **Janine Benyus's** articulation of *biomimicry* as a design philosophy
- **Len Troncale's** *Systems Processes Theory*, which identifies recurring system processes across natural and artificial systems
- **Lynn Rasmussen's** *Seeing*, which visualizes patterns and rhythms in living systems as design referents for system dynamics

These contributions illustrate that nature does not merely inspire aesthetics, it offers scalable, transdisciplinary insights that can ground both practice and theory.

Systems Engineering Benefits Across Levels

Level	Benefit
Project	More robust, adaptive, and context-sensitive designs; reduced failure modes and lifecycle vulnerabilities
Organizational	Facilitates interdisciplinary collaboration across science, engineering, ecology, and sustainability
Professional	Deepens creative and ethical engagement with complex challenges; supports careers attuned to 21st-century imperatives
Societal	Contributes to regenerative, equitable, and sustainable system outcomes aligned with long-term planetary viability

A Responsibility to Design Within and With Nature

Nature is not merely a constraint, it is a **partner, precedent, and teacher**. As engineering increasingly intersects with planetary limits, it becomes vital to:

- **View Earth as a system-of-systems**, not a passive backdrop
- **Recognize and value ecosystem services** as part of design trade-offs
- **Design systems that co-evolve with their environments**, respecting scale and phase relationships
- **Foster long-term viability**, regeneration, and fairness, not just short-term output and optimization

This perspective contributes to an emerging **ethics of systems** grounded in **stewardship, relationality, and life-enhancing reciprocity**.

Toward a Nature-Informed Paradigm

As systems engineers confront 21st-century challenges, such as changing climate, advancement of cyber-physical systems, and space exploration, natural systems provide not only technical inspiration but also a paradigm for sustainability and stewardship. Recognizing the Earth as a system of systems encourages the design of human systems that thrive with, rather than at the expense of, the natural environment.

Significant System of Systems Reference Models:

- Ecosystems: Forests, Coral Reefs, or Grasslands can provide insights into how diverse components continually self-organize.
- Biological Processes: Photosynthesis, Decomposition, or Nutrient Cycling can reveal evolved patterns of energy conversion, waste management, and resource allocation.
- Geological Systems: Plate Tectonics, Weathering, or Erosion can provide perspectives on long-term change, stability, and different components of the Earth's system.
- Atmospheric and Oceanic Processes: Circulation patterns, Currents, and Mass-Energy Balance can inform our understanding of global systems, feedback loops, and the interconnectedness of our planet.
- Critical Zone Interfaces: The dynamic and complex interactions between the atmosphere, biosphere and geosphere can offer insight into how nature operates through multiple levels and scales of complexity, highlighting functional exchanges of material and energy at the system boundaries.

The benefits of incorporating natural systems thinking also extend beyond individual projects. At an organizational level, it can create productive intersections between scientific, technological, and engineering functions. At a professional level, it fosters creativity, engagement, and satisfaction in developing holistic solutions. At a societal level, it supports the design of systems that are more sustainable and more symbiotic with their natural counterparts (Ostrom 2009; Volk 2017).

Ultimately, integrating knowledge of natural systems into systems engineering can improve outcomes across the lifecycle—enhancing performance, value, and sustainability. It also strengthens awareness of the Earth as a system-of-systems, highlighting the value of ecosystem services and the responsibility to design human systems that thrive with, rather than at the expense of, natural systems.

Systems are distinguished not only by what they do, but by what they are. This article explores two foundational and interdependent properties of all systems: **identity**, which sustains their distinctiveness and coherence, and **togetherness**, which enables the organization and integration of parts into functioning wholes. Together, these properties underpin system persistence, adaptation, and recognition across scales.

This article complements other entries in this knowledge area that examine behavior, purpose, value, and cycles, offering systems engineers a deeper understanding of how systems maintain continuity while participating in complex, evolving environments.

Introduction: Identity, the Persistence of Distinctiveness

Identity and togetherness are fundamental properties of systems that underpin their recognition, persistence, and coherence. *Identity* refers to what makes a system distinct from its environment, while *togetherness* refers to the forces and organizing principles that bind components into a functioning whole. These concepts are central to understanding Form in the Fit–Form–Function framework and are essential for defining, modelling, and engineering systems of interest.

In natural systems, identity is expressed through mechanisms such as atomic structure, genetic codes, or ecological niches, while togetherness emerges from binding forces, membranes, flows, and interdependencies. In social systems, shared values and institutions sustain collective identity and cohesion. Engineered systems achieve identity and togetherness through standards, interfaces, and architectures that stabilize interactions across components and stakeholders.

Patterns of identity and togetherness can be observed across levels of emergence, from quarks and molecules to ecosystems, societies, and systems of systems. At each level, new forms of binding lead to new forms of identity: particles form atoms, cells form organisms, and institutions form cultures and enterprises. This progression illustrates how complexity grows through successive layers of coherence.

For systems engineering, attention to identity and togetherness has practical implications. Defining the System of Interest (SoI) requires clarity of boundaries and coherence. Modularity and cohesion guide system integration and interoperability. Identity supports verification, validation, and lifecycle continuity. At enterprise and SoS scales, maintaining togetherness across independent systems requires governance, shared purpose, and mission alignment. Finally, recognizing the togetherness of human systems with natural systems emphasizes the need for sustainable and symbiotic design.

By studying identity and togetherness, systems engineers and practitioners gain a foundation for addressing complexity, ensuring resilience, and designing systems that persist and adapt within broader contexts.

Definitions and Perspectives

- **Identity**: refers to the enduring properties by which a system is recognized as the same system over time, even as its components and context may change. It arises from:
  - **Structure:** The pattern of internal relationships that provide cohesion and functional capability.
  - **Boundaries:** A distinction from the surrounding environment, whether physical, informational, or conceptual.
  - **History:** Continuity through memory, record, or inherited structure (e.g., genetic code, configuration baselines).
  - **Intent:** In engineered systems, purpose contributes to identity, what the system is *for* shapes what it *is*. Systems engineers commonly encounter identity in the form of **system-of-interest (SoI)** boundaries, configuration states, mission definitions, and stakeholder values. However, identity is also an emergent, relational phenomenon—it is not always fixed, and in socio-technical or natural systems, may evolve or be contested..
- **Togetherness**: refers to the organizing forces, constraints, or relations that bind a system's parts into a coherent whole. This includes:
  - **Binding Forces:** Physical (e.g., gravity, electromagnetism), informational (e.g., feedback), or organizational (e.g., hierarchy, contracts).
  - **Interdependence:** Components rely on one another to fulfill system functions.
  - **Integration Mechanisms:** Interfaces, modularity, and protocols enable cooperation and coordination.
  - **Contextual Unity:** Shared environment or purpose that drives collective behavior. In engineering practice, togetherness shows up in **systems integration**, **interface control**, **team dynamics**, and **value co-creation**. The stronger and more aligned the forces of togetherness, the more functional and resilient the system..

Perspectives from systems science include:

- **General Systems Theory** (Boulding, 1956): Identity persists through levels from structures to transcendent systems.
- **Relational Science** (Kineman, 2011): Identity emerges through a system's relation to self, others, and whole.
- **Holonic Models** (Koestler, 1967): Systems as nested wholes/parts, each with autonomous identity and embeddedness.
- **Pattern Science** (Troncale, 1978; Rasmussen, 2024): Identity arises from pattern recurrence, togetherness from coupling processes.

Patterns and Archetypes of Identity & Togetherness

Identity and togetherness emerge through recurring archetypes across levels of scale. Each level demonstrates how binding mechanisms create coherence and how new forms of identity arise. These archetypes also provide analogies useful for systems engineering practice.

Quarks and Atoms

- *Binding:* Strong and electromagnetic forces hold particles together.
- *Identity:* Stable elements with distinctive properties.
- *Engineering Analogy:* Interface standards act like physical forces, binding components into stable configurations while preserving distinct properties (e.g., USB, TCP/IP).

Molecules

- *Binding:* Chemical bonds integrate atoms into compounds with new behaviours.
- *Identity:* Distinct compounds with emergent properties beyond their elements.
- *Engineering Analogy:* Software modules or hardware components bound by design rules; emergent system behaviour arises from well-structured integration.

Cells

- *Binding:* Membranes, genetic codes, and metabolic cycles maintain integrity.
- *Identity:* The cell as a self-sustaining unit of life.
- *Engineering Analogy:* Subsystems with clear boundaries and internal processes (e.g., avionics suites, autonomous vehicles) that preserve autonomy while interacting with wider systems.

Organisms

- *Binding:* Physiology, behaviour, and coordination of subsystems.
- *Identity:* The organism as a functioning individual capable of adaptation.
- *Engineering Analogy:* Complex engineered products (e.g., aircraft, satellites) that integrate diverse subsystems into a coherent, adaptive whole.

Ecosystems

- *Binding:* Energy flows, interdependence, and ecological niches.
- *Identity:* The ecosystem as a resilient, adaptive collective.
- *Engineering Analogy:* System-of-systems such as transportation networks or power grids, where diversity and redundancy enhance resilience.

Societies

- *Binding:* Shared values, culture, and institutions sustain collective identity.
- *Identity:* The society as a coordinated human system.
- *Engineering Analogy:* Enterprises and large-scale programs, where governance, standards, and culture bind people and technologies into effective organizations.

Cultures, Enterprises, and Systems of Systems (SoS)

- *Binding:* Governance structures, shared purpose, and adaptive institutions.
- *Identity:* The adaptive whole, capable of learning and transformation.
- *Engineering Analogy:* Multi-stakeholder SoS (e.g., smart cities, global telecommunications) where coherence depends on aligning governance, mission, and interoperability across independently managed systems.

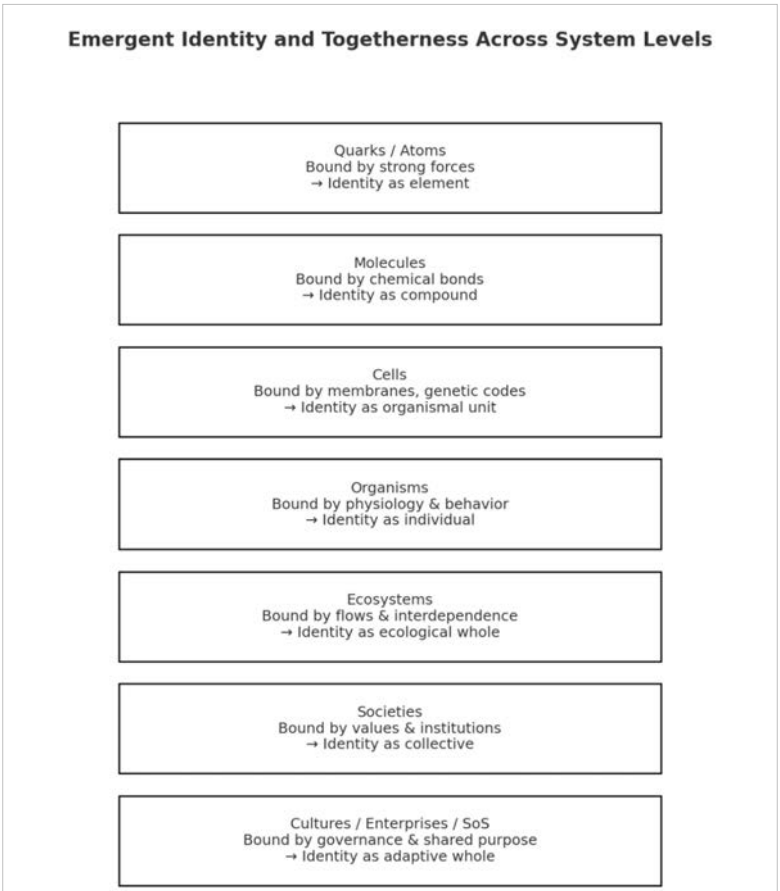

Figure 1: Identity and Togetherness of Systems (SEBoK Original)

Figure 1 (Archetypes of Identity and Togetherness Across System Levels) illustrates this progression. At each step, new forms of togetherness enable the emergence of new identities, providing both inspiration and analogy for engineered systems.

Identity and togetherness shape all stages of the systems engineering life cycle:

- **System of Interest and Requirements**: Defining identity clarifies scope, boundaries, and stakeholder needs. Poorly specified identity often leads to scope creep or mismatched expectations (e.g., aerospace programs with shifting SoI definitions).
- **Architecture and Design**: Togetherness informs modularity, cohesion, and interoperability. Standards and protocols provide “membranes” for interaction, as in Modular Open System Architectures (MOSA).
- **Integration, Verification, and Validation**: Preserving identity ensures continuity and traceability across lifecycle stages. Togetherness supports reliable integration without loss of coherence.
- **Enterprise and System of Systems Engineering**: Identity at scale is maintained through governance, shared mission, and institutional alignment. Smart city SoS, for example, require governance frameworks to sustain coherence across autonomous subsystems.
- **Sustainability and Ecological Context**: Engineered systems always interact with natural systems. Designing for sustainability requires respecting ecological identities and fostering symbiotic forms of togetherness (e.g., circular resource flows, ecosystem resilience).

In practice, identity defines *what the system is*, while togetherness guides *how the parts are bound*. Integrating these concepts explicitly into lifecycle activities enables engineers to manage complexity, ensure resilience, and design systems that are effective, sustainable, and adaptive.

Implications for Systems Engineering

Attention to identity and togetherness strengthens the conceptual foundation of systems engineering by clarifying what gives a system coherence, persistence, and purpose across its life cycle. These principles illuminate the underlying logic of ISO/IEC/IEEE 15288 processes and support the broader aims of INCOSE Vision 2035 to engineer "solutions for a better world."

Defining and Maintaining System Identity

Identity provides the basis for distinguishing the System of Interest (SoI) from its environment. Establishing and maintaining this identity enables clear scope definition, stakeholder alignment, and configuration control. Through life-cycle stages, traceability of requirements, architecture, and verification activities depends on the persistence of system identity. When identity becomes ambiguous, boundaries blur, leading to scope creep, fragmented ownership, and loss of coherence.

Achieving Coherence through Togetherness

Togetherness expresses the organizing principles that bind parts into functioning wholes. In engineering terms, this corresponds to modularity, cohesion, and well-defined interfaces that enable integration while preserving autonomy. Standards and protocols act as the "binding forces" of engineered systems, ensuring predictable interaction among subsystems. Applying these principles supports reliable integration and effective interoperability across suppliers and organizations.

Supporting Lifecycle Continuity and Change

Systems evolve through upgrades, maintenance, and contextual change. Understanding how togetherness operates allows engineers to manage change without eroding system integrity. Configuration management, interface control, and verification and validation all rely on maintaining the balance between preserving identity and accommodating adaptation.

Governance and Alignment in Enterprises and Systems of Systems

At enterprise and SoS scales, identity equates to shared purpose and mission coherence among independently managed systems. Togetherness is achieved through governance, standards, and culture that sustain collaboration and mutual trust. Effective SoS engineering depends on these higher-order forms of cohesion as much as on technical interoperability.

Sustainability and Societal Integration

Engineered systems inevitably interact with natural and social systems. Recognizing the togetherness of human and ecological systems highlights the responsibility to design for sustainability. Identity must extend beyond the engineered artifact to include its role within broader environmental and societal contexts. Concepts such as circular resource flows, resilience, and regenerative design exemplify this systems-level coherence.

Methodological Implications

Incorporating identity and togetherness encourages a shift from purely reductionist decomposition toward re-compositional and coherence-based design. Systems engineers can use these principles as diagnostic lenses to assess systemic integrity, identify weak coupling or fragmentation, and guide integration strategies that reinforce coherence across boundaries and life-cycle stages.

Summary

By embedding the principles of identity and togetherness within systems engineering practice, engineers can design and sustain systems that remain coherent, resilient, and ethically aligned with their wider human and ecological environments. These concepts provide a bridge between systems science and engineering application, clarifying how systems maintain continuity through change and how collective purpose and structure emerge from well-governed interconnection.

This article is part of The Nature of Systems area (KA). The article reflects established knowledge from systems science and systems engineering, organized and collated for the SEBoK. Drafting support was provided by OpenAI's ChatGPT, with all content reviewed and finalized by the author, who retains full responsibility.

Introduction

Behaviour and dynamics describe how systems act and change over time. *Behaviour* refers to the externally observable responses or outputs of a system, while *dynamics* refers to the internal processes and interactions that give rise to these behaviours. Together, they provide an internal perspective on **Form**, complementing concepts such as identity and togetherness, and distinct from the temporal rhythms described in *Cycles and Phases of Systems*.

Understanding behaviour and dynamics is critical for systems engineers. Internal dynamics such as feedback, thresholds, and attractors shape how systems behave under stress, adapt to change, or collapse into dysfunction. These mechanisms underpin, but are not the same as, the recurring temporal patterns of Function described in *Cycles and Phases*.

Definitions and Perspectives

- **Behaviour:** The observable outcomes of a system as it interacts with its environment.
- **Dynamics:** The internal mechanisms, feedback, flows, state transitions, that drive and constrain behaviour.

Key perspectives include:

- Levels of system behaviour from simple reactive to goal-seeking and learning (Boulding 1956)
- System dynamics, focusing on stocks, flows, and feedback loops (Forrester 1961)
- Systems isomorphies such as Feedback, Oscillation, and Regulation Troncale (2001)
- Anticipatory systems, where internal models shape behaviour (Rosen 1985).
- Principles of systemic dynamics including stability, chaos, and adaptation (Mobus & Kalton 2015)

Transversal Context

Examples across domains illustrate how dynamics generate behavior:

- **Physical systems:** oscillations of a pendulum, turbulence, critical transitions in fluids.
- **Biological systems:** homeostasis, neural firing, adaptation to stimuli.
- **Ecological systems:** predator–prey growth and decline, resilience, sudden regime shifts.
- **Social systems:** reinforcing loops in markets, diffusion of innovations, collective behaviours.
- **Engineered systems:** feedback control in aircraft, congestion dynamics in networks, emergent effects in software.

These cases show that while behaviour is what we observe, it is dynamics that explain *why* systems act as they do.

Patterns and Archetypes of System Behaviour and Dynamics

Systems exhibit recurring dynamic modes generated by internal mechanisms such as feedback, nonlinearity, and state dependence. These archetypes form the **mechanistic basis** for the cycles and phases described in the companion article *Cycles and Phases of Systems*.

Stability and Equilibrium

- **Description:** A system resists change and maintains its state through balancing feedback.
- **System example:** The body's temperature regulation through sweating and shivering.
- **Engineering example:** An aircraft autopilot holding altitude by adjusting control surfaces.
- **Lesson for SE:** Stability depends on effective balancing feedback and control; poorly tuned loops can cause drift or oscillation.

Oscillation and Feedback Loops

- **Description:** Interactions of reinforcing and balancing loops generate cycles around an equilibrium.
- **System example:** Predator–prey population swings in ecosystems.
- **Engineering example:** Underdamped suspension systems producing oscillations in vehicles.
- **Lesson for SE:** Oscillations can be beneficial (rhythmic processes) or harmful (instability); understanding feedback strengths is critical.

Attractors and Dynamic Regimes

- **Description:** Systems converge toward stable points, cycles, or chaotic attractors that define long-term behaviour.
- **System example:** The Lorenz "butterfly" attractor in weather models.
- **Engineering example:** Internet traffic stabilizing at a particular level of congestion.
- **Lesson for SE:** Attractors help anticipate possible end states; design should account for which regime the system may settle into.

Nonlinear Growth and Saturation

- **Description:** Reinforcing feedback leads to exponential growth until constraints produce saturation.
- **System example:** Logistic growth of bacteria in a nutrient-rich medium.
- **Engineering example:** Adoption of new technologies following an S-curve.
- **Lesson for SE:** Anticipating resource constraints and saturation points avoids overdesign and unexpected decline in performance.

Criticality and Tipping Points

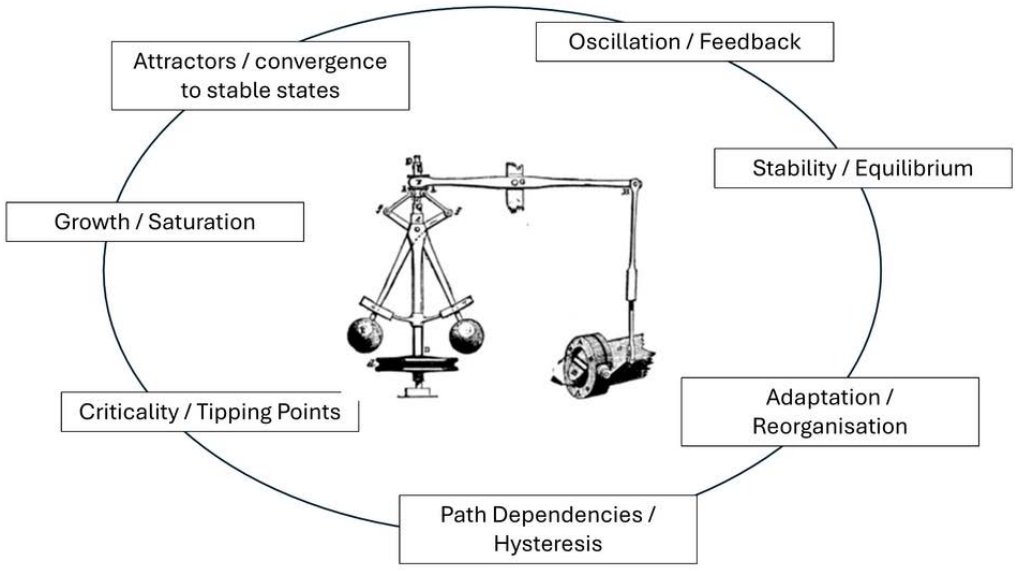
- **Description:** Small changes can push systems across thresholds, causing large regime shifts.
- **System example:** Sudden collapse of fisheries once population drops below a critical threshold.
- **Engineering example:** Cascading failures in a power grid triggered by a single line outage.
- **Lesson for SE:** Early warning indicators of criticality (stress, load, redundancy loss) are essential for risk management.

Path Dependence and Hysteresis

- **Description:** The trajectory of system behavior depends on past states, and recovery does not follow the dame path as decline.
- **System example:** Ecosystems degraded by deforestation may not recover even if regrowth occurs.
- **Engineering example:** Legacy IT systems locking organizations into architectures that are difficult to replace.
- **Lesson for SE:** History matters; decisions create lock-in, so architects should anticipate long-term dependencies.

Adaptive Dynamics

- **Description:** Systems may reorganize their internal structures and feedback processes in response to disturbances, producing new modes of behavior.
- **System example:** An ecosystem reorganizing after a disturbance, shifting species dominance but maintaining function.
- **Engineering example:** Resilient infrastructure rerouting flows after a component failure.
- **Lesson for SE:** Adaptive dynamics increase resilience by enabling systems to absorb shocks and reconfigure, but can also introduce unpredictability and unintended consequences.



Governor and Throttle-Value. Figure 4. By R. Routledge - Image from "Discoveries & Inventions of the Nineteenth Century" by R. Routledge, 13th edition, published 1900., Public Domain.

Figure 1: Archetypes of System Behaviour and Dynamics (SEBoK Original)

This figure illustrates seven archetypal modes of system dynamics: stability, oscillation, attractors, growth, criticality, path dependence, and adaptive dynamics. The Watt flyball governor, shown at the centre, symbolizes the internal mechanisms of feedback and regulation that generate such behaviours.

The governor demonstrates in mechanical form how centrifugal force, feedback, and thresholds can stabilize a system against perturbations, or, if mis-tuned, lead to oscillation and collapse. Similarly, across natural, social, and

engineered systems, internal processes such as balancing and reinforcing feedback, attractors, and nonlinear thresholds drive recurrent dynamic modes.

These archetypes provide analogies for systems engineering practice:

- Stability in control loops and architectural balance.
- Oscillation in under-damped systems or cyclical market behaviours.
- Attractors in enterprise dynamics and traffic flow equilibria.
- Growth and saturation in technology adoption.
- Criticality in cascading failures such as power grids.
- Path dependence in legacy architectures.
- Adaptive reorganization in resilient infrastructures.

By focusing on dynamics as the *engine* of behaviour, the figure highlights how internal processes shape observable system outcomes, and how understanding these mechanisms helps systems engineers anticipate, design for, and manage complex behaviour.

Theories and Frameworks

- Models using stocks, flows, and feedback - **System Dynamics** (Forrester 1961, Meadows et al 1972)
- Regulation, homeostasis, and purposeful feedback control - **Control Theory** (Aström, Murray. 2008) **and Cybernetics** (Wiener 1948)
- Emergent behaviors, criticality, sensitivity to initial conditions - **Chaos** (Gleick 1978) **and Complexity** (Mitchell 2009).
- Domain-independent isomorphies of feedback, oscillation, and regulation - **Systems Processes Theory** (Troncale 2014).
- Systems that model their environment internally and respond proactively - **Anticipatory Systems** (Rosen 1985)

Implications for Systems Engineering

System dynamics have direct consequences across the lifecycle:

- **Requirements and SoI Definition:** Anticipating desired behaviors requires attention to dynamic mechanisms, not just static functions. Poorly specified dynamics can produce instability or unintended responses.
- **Architecture and Design:** Togetherness of parts must be structured through feedback and control. Examples include avoiding oscillations in flight control or ensuring damping in mechanical systems.
- **Modelling and Simulation:** Dynamic models such as system dynamics, MBSE, agent-based simulation, are vital tools to test how internal processes shape external behaviour.
- **Integration, Verification, and Validation:** Traceability depends on ensuring that the integrated dynamics generate the intended behaviours across conditions.
- **Risk and Safety:** Understanding reinforcing loops, tipping points, and collapse dynamics is essential to preventing failure cascades (e.g., power grid blackouts).
- **Enterprise and SoS Engineering:** Emergent dynamics arise from interactions among independently managed systems; governance and coordination are needed to maintain coherence.
- **Sustainability:** Designing with feedback from natural and social systems in mind helps create resilient and adaptive engineered systems.

Framing and Definitions

This article is part of The Nature of Systems knowledge area (KA). **Cycles** and **Phases** are general system concepts studied across many sciences and recognized as fundamental patterns of Function. They complement the Form-focused concepts of identity, togetherness, behavior, and dynamics, by describing how systems unfold and repeat through time:

- Cycles refer to patterns of **recurrence** - sequences of events that return to their starting conditions or repeat in recognizable rhythm.
- Phases refer to patterns of **progression** - the sequential stages through which systems emerge, develop, mature, decline, or transform

Crucially, **each phase is characterized by distinctive underlying behaviors and functions, not simply by its position in sequence**. For example:

- Early phases emphasize **exploration** and **innovation**.
- Growth phases emphasize **structuring** and **scaling**.
- Maturity phases emphasize **conservation** and **optimization**.
- Decline and release phases emphasize **breakdown** and **transformation**, opening the way for renewal.

Several definitions illustrate the breadth of the cycle concept:

- "A series of events that are regularly repeated in the same order; or move in or follow a regularly repeated sequence of events." — Oxford English Dictionary
- "Cycles define and make things. Equally things contain cycles." — (Volk 1995)
- "A temporal pattern." — (Mobus and Kalton 2015)
- "The longer and more regular the series is repeated, the more predictable it becomes, until it cannot reasonably be considered a coincidence." — Foundation for the Study of Cycles
- "Circularity is the essence of the early notion of feedback (circular causality). The notion of circularity is found in recursive computation (the use of DO loops, for example)." — (Krippendorff 1984)

Phases are equally universal. Troncale (1978) observed that "all living (even non-living) entities of the same class exhibit the same phases in their life cycle – birth, maturation, death, dissolution." Such phase patterns are instantiated in natural systems, ecological succession, social processes, and engineered lifecycles.

Position in the Fit–Form–Function Framework:

- **Form concepts** (identity, togetherness, behavior, dynamics) describe what a system is and how it acts internally.

- **Function concepts** (cycles, phases, purpose, capabilities) describe what a system does through time and the recurring temporal structures it expresses.
- **Cycles** and **Phases** are the first major categorization of Function, forming a bridge between the internal dynamics of systems and the observable patterns of activity that structure their engagement with context.

Introduction: Ubiquity of Cycles and Phases

Movement and evolution are fundamental in the dynamics of nature, and cycles and phases are evident across nearly every domain of inquiry. Because of their generality, they are key concepts for Systemists they provide a common language, inspire systemic thinking, and offer practical means for engaging with systems.

- **Cycles** appear as repeated patterns or rhythms of activity, from planetary orbits and ecological renewal to decision-making routines and enterprise management. They provide continuity and predictability by connecting events across time.
- **Phases** appear as ordered stages of progression, such as birth, growth, maturity, decline, and renewal in both living and non-living systems. Each phase expresses distinctive behaviors and functions, shaping the way systems interact with their environment and with one another.

Examples across the sciences illustrate their ubiquity:

- **Ecology**: adaptive cycles of exploitation, conservation, release, and reorganization (Allen & Hoekstra 1992; Gunderson 2013).
- **Social science**: planning and intervention cycles, often structured as sequential phases of inquiry and action (Sankaran et al. 2015).
- **Business and learning**: reinforcing cycles of cause and effect, as in Senge's insight that *"today's problems come from yesterday's solutions"* (Senge 2006).
- **Cybernetics**: circular causality and feedback cycles that underpin control and regulation (Krippendorff 1984).
- **Physics**: coherence and decoherence cycles in quantum mechanics (Hsiang & Ford 2009).
- **Systems biology**: modeling and interpretation cycles in living systems (Rosen 1991a, 1991b).

Cycles and phases are equally evident in engineered practice:

- Project and system lifecycles,
- Enterprise planning horizons,
- Iterative and spiral development methods,
- The recursive structure of the scientific method itself.

Together, these examples demonstrate that cycles and phases are among the most pervasive and useful concepts in systems science. They provide one of the most powerful entry points for recognizing **Function** in systems, linking natural phenomena, social processes, and engineered practice.

Cycles and Phases in Frameworks

Cycles and phases are embedded in frameworks that guide inquiry, management, and engineering practice. These illustrate how recurrence and progression structure systemic understanding and action.

- **Cynefin Framework –** A situational sense-making model highlighting transitions between ordered, complex, and chaotic domains. These transitions represent *phases* of context, while iterative exploration and re-categorization illustrate *cycles* of learning and adaptation.
- **Panarchy –** A theory of adaptive cycles in ecosystems and social–ecological systems (Gunderson & Holling 2002). It describes *phases* of exploitation, conservation, release, and reorganization, while *nested cycles* link local dynamics with broader cross-scale interactions.
- **OODA Loop –** The Observe–Orient–Decide–Act decision framework developed in military contexts. It presents a sequential set of *phases* that, when repeated rapidly, form a *cycle* enabling agility under pressure.

- **Spiral Model of Software Development –** An iterative engineering lifecycle combining sequential *phases* (requirements, design, implementation, testing) with recurring *cycles* of refinement and risk assessment.
- **Problem/Solution Systems and Action Research –** Frameworks such as Plan–Act–Observe–Reflect represent explicit *phases* of inquiry, embedded in recursive *cycles* of practice and reflection that build cumulative learning.
- **Senge's First Law –** *"Today's problems come from yesterday's solutions"* (Senge 2006). This highlights the recursive nature of interventions, in which each solution cycle produces conditions that shape subsequent *phases* of systemic response.
- **Relational Holon –** Building on Rosen and extended by Kineman, the holon models the reciprocity of system and context. It frames *phases* of origin, realization, interaction, and transformation as aspects of a recurring *cycle* that repeats across scales of organization.
- **Life Cycle Management –** The management of software, products, services, and enterprises is structured by sequential *phases* of concept, development, operation, and retirement, interwoven with renewal *cycles* such as upgrades and iterations.
- **Scientific Method –** A canonical example of sequential *phases* (hypothesis, experiment, analysis, conclusion) that are repeated across *cycles* of inquiry to build cumulative knowledge.
- **Systems Engineering Life Cycle –** The discipline of systems engineering itself is organized around project *phases* (concept, development, operation, retirement) linked by iterative *cycles* of feedback, review, and refinement.

Together, these frameworks demonstrate that cycles and phases are not abstractions but **operational tools**, shaping how problems are framed, solutions are developed, and systems are managed across contexts. They also reveal a pattern: **phases provide structure for progression, while cycles enable iteration and renewal**, a distinction that will be integrated in the models and archetypes described in the following sections.

Integrated Models of Cycles and Phases

While individual frameworks illustrate specific forms of recurrence and progression, some models demonstrate how cycles and phases can be aligned across theory and practice. These integrations show coherence between systemic concepts and engineering application.

- **Systems Engineering Lifecycle and Relational Holon –** The phases of the systems engineering lifecycle (concept, development, operation, retirement) can be mapped onto the relational holon's phases of origin, realization, interaction, and transformation. This highlights how theoretical models of system–context reciprocity can inform practical engineering lifecycles.
- **Cynefin and Lifecycle Phases –** The Cynefin framework complements lifecycle thinking by showing how sense-making transitions (ordered ↔ complex ↔ chaotic) align with, or disrupt, engineering phases. This helps practitioners recognize when iterative cycles are required rather than linear progression.

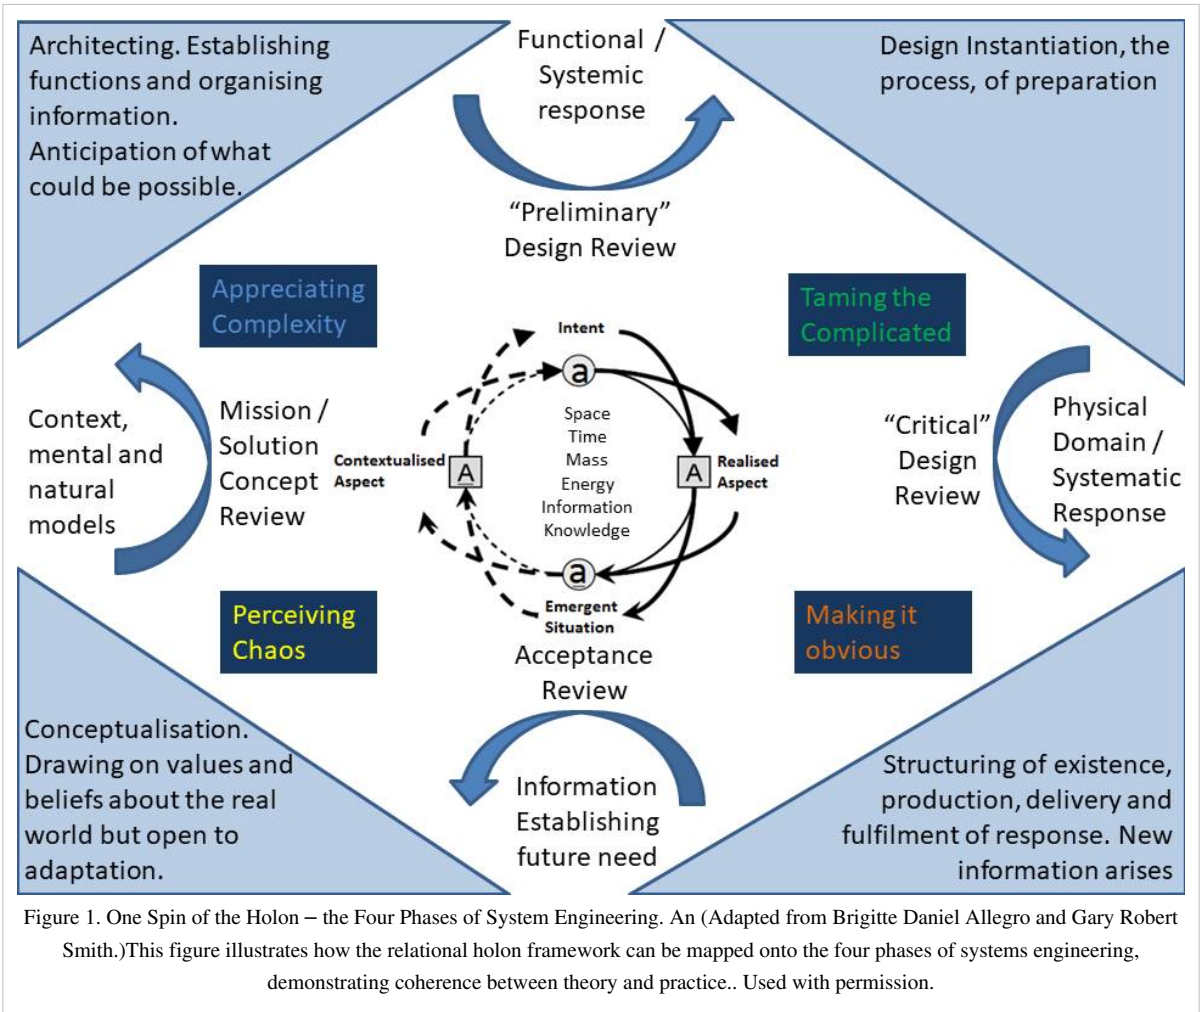

Figure 1. One Spin of the Holon – the Four Phases of System Engineering. An (Adapted from Brigitte Daniel Allegro and Gary Robert Smith.)This figure illustrates how the relational holon framework can be mapped onto the four phases of systems engineering, demonstrating coherence between theory and practice.. Used with permission.

Further integrative perspectives have been contributed through the International Society for the Systems Sciences (ISSS). These include Len Troncale's *Unbroken Sequence of Origins*, which postulates recurrent patterns of system emergence, and Tyler Volk's *metapatterns*, which reveal binding, breaking, and renewal cycles across domains. Video contributions by Troncale, Volk, and Smith further illustrate how cycles and phases connect scientific insight with systems practice (ISSS Cycle Contributions) [1].

Recurrent Isomorphies

Beyond applied frameworks, cycles and phases can be understood as **isomorphic processes,** recurring systemic patterns observed across multiple domains of science. These provide a deeper theoretical grounding for systems science and practice.

(Troncale 1978) systematically documented recurrent patterns of cycling, showing evidence of over 250 natural and social phenomena across seven major scientific disciplines. This work forms part of *Systems Process Theory*, which seeks to identify the universal processes underpinning system behavior and to establish a unifying empirical foundation for systems science.

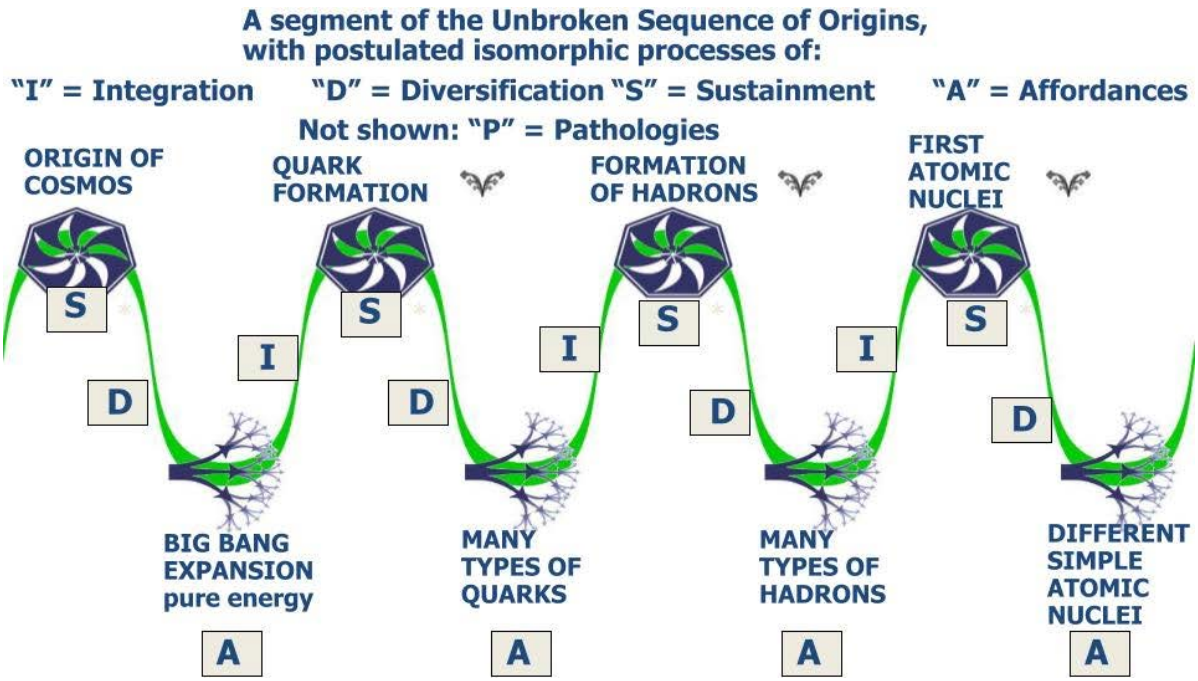

Figure 2. Recurrent Pattern of Isomorphic Processes Across the Unbroken Sequence of Origins.*(Adapted from Len Troncale; ISSS Cycle Contributions).* (Used with permission)

This figure illustrates a waveform pattern of recurrent processes and phases spanning the Unbroken Sequence of Origins. Troncale observed that "all living (and even non-living) entities of the same class exhibit the same phases (form) in their life cycle – birth, maturation, death, dissolution." Subsequent collaborative work extended this pattern to include additional processes such as affordances (opening new relational possibilities) and sustainment (maintenance of systemic coherence).

These recurrent isomorphies show that cycles and phases are not arbitrary constructs but reflect enduring structures of reality. By recognizing and classifying these universal processes, systemists and engineers can design, maintain, and apply lifecycle processes with greater fidelity. In this sense, isomorphies provide a scientific foundation for connecting systemic Function to practical systems engineering.

Archetypes of Cycles and Phases

Cycles and phases can be abstracted into **archetypes —** recurrent patterns that generalize across domains of science, society, and engineering. Archetypes make the underlying logic of cycles and phases tangible, and provide a bridge between systemic theory and practical application.

Cycle Archetypes

Cycle archetypes emphasize **recurrence and rhythm —** the repeating patterns that sustain systems over time.

- **Feedback Loops –** reinforcing or balancing interactions that generate recurrence.
  - Found in ecological predator–prey oscillations, organizational decision loops, and engineering control systems.
- **Iterative Cycles –** repetition with refinement, building cumulative improvements.
  - Evident in scientific experimentation, agile sprints, and spiral development models.
- **Nested Cycles –** cycles within cycles operating at multiple scales.
  - Examples include ecological panarchy (local ↔ global) or enterprise planning cycles embedded within strategic horizons.
- **Coupled Cycles –** interacting cycles that synchronize or conflict with one another.

- Examples include economic and political cycles, or product refresh cycles interacting with regulatory approval cycles.

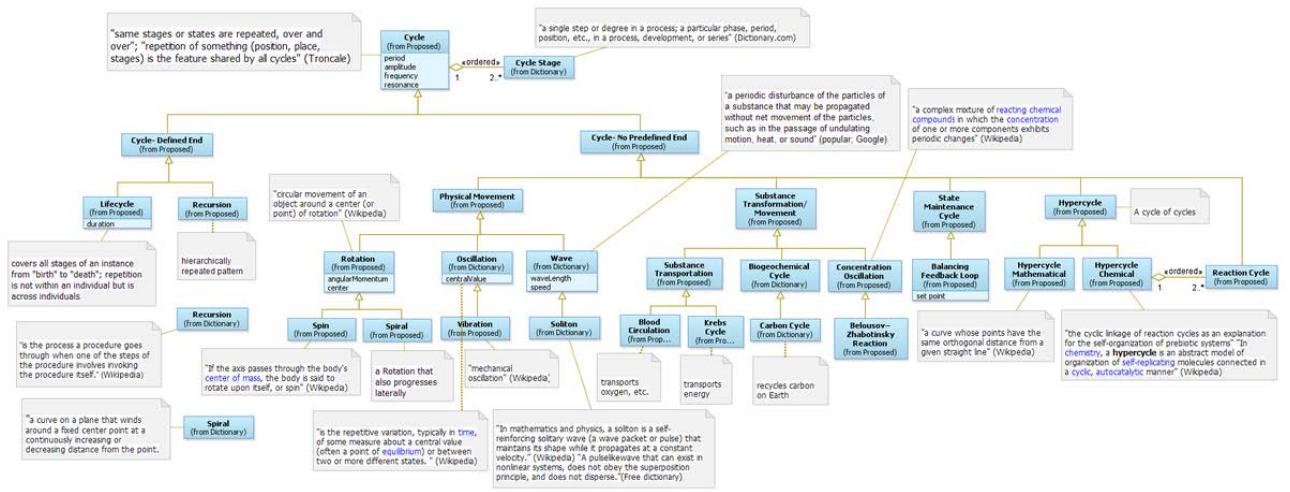

Figure 3. **Archetypes of Cycle.** (Marzolf 2020) ISSS Cycle Contributions. https://www.isss.org/sebok-contribution/Used with Permission

Cycles manifest across domains as feedback, iteration, nesting, and coupling. Each archetype captures a distinctive way in which recurrence is structured and maintained. These archetypes provide analogies for engineering practice, supporting system control, iterative design, multi-level management, and coordination across interdependent cycles.

Phase Archetypes

Phase archetypes emphasize **progression and transformation**, the ordered stages through which systems evolve. Each phase expresses **distinctive behaviors and functions**:

- **Life Phases –** exploration (birth), structuring (growth), optimization (maturity), release (decline), renewal (reorganization).
  - Found in organisms, stars, and engineered product lifecycles.
- **Adaptive Cycles –** exploitation → conservation → release → reorganization.
  - Widely used to describe ecosystem resilience and enterprise renewal.
- **Development Phases –** design, build, operate, sustain.
  - Common to engineered projects, infrastructure systems, and the SE V-model.
- **Decision Phases –** observe, orient, decide, act.
  - Characterize situational decision-making and agile team practices.

Recognizing these archetypes reinforces that phases are not arbitrary labels but **distinct systemic states** with characteristic behaviors and functions.

Integrative Archetypes

Some systemic models combine cycles and phases, illustrating how **recurrence and progression interrelate**:

- **Troncale's isomorphies –** recurrent processes that manifest as ordered sequences of phases across the *Unbroken Sequence of Origins*.
- **Volk's metapatterns –** binding, breaking, and renewal cycles repeated across levels of emergence.
- **Relational Holon –** reciprocal phases of origin, realization, interaction, and transformation, embedded in cyclical relation between system and context.
- **Systems Engineering Lifecycles –** sequential phases (concept, development, operation, retirement) structured by iterative cycles of review and renewal.

Together, these archetypes demonstrate that:

- **Cycles structure recurrence.**
- **Phases structure progression.**
- **Integrative archetypes connect the two**, showing how systemic Function arises from the interplay of recurring rhythms and ordered transformations.

Implications for Systems Engineering

Cycles and phases underpin many methods and lifecycles in systems engineering. Recognizing their archetypes enables practitioners to align practice with systemic Function, anticipate transitions, and design for resilience.

- **Concept Definition**
  - *Phase archetype (life phases – birth)*: emphasizes exploration, creativity, and innovation.
  - *Cycle archetype (feedback loops)*: stakeholder engagement and iterative feedback ensure robustness of early concepts.
- **Design and Development**
  - *Phase archetype (growth)*: emphasizes structuring, scaling, and alignment of resources.
  - *Cycle archetype (iterative cycles)*: spiral development and agile sprints support progressive refinement.
  - *Integrative archetype (relational holon) (Blockley 2022)*: highlights the reciprocity of system–context relations in design choices.
- **Integration, Verification, and Validation (V&V)**
  - *Phase archetype (maturity)*: emphasizes assurance, stability, and optimization of function.
  - *Cycle archetype (feedback loops)*: V-model structures link requirements definition to validation, closing the loop.
  - *Phase archetype (decision phases)*: V&V reviews can be structured as OODA loops, supporting adaptive decision-making.
- **Operation and Sustainment**
  - *Phase archetype (maturity/conservation)*: emphasizes reliability, optimization, and efficiency.
  - *Cycle archetype (renewal cycles)*: upgrades, maintenance, and feedback-informed adjustments sustain long-term performance.
- **Retirement and Renewal**
  - *Phase archetype (decline/release and reorganization)*: emphasizes transformation, resource recovery, and closure.
  - *Cycle archetype (nested cycles)*: feedback from decommissioning informs the birth of next-generation systems.
- **Enterprise and System of Systems (SoS)**
  - *Cycle archetypes (nested and coupled cycles)*: illustrate how enterprise planning horizons, regulatory cycles, and product lifecycles must be harmonized.

    - *Integrative archetypes (panarchy)*: reveal how cross-scale cycle alignment supports systemic resilience.
- **Risk and Resilience**
    - *Phase archetype (adaptive cycle transitions)*: tipping points occur at shifts from conservation to release, highlighting fragility.
    - *Cycle archetype (critical feedback loops)*: reinforcing loops can escalate into cascading failures, while balancing loops maintain resilience.
- **Sustainability and Long-Term Viability**
    - *Integrative archetypes (ecological and societal cycles)*: engineered systems exist within planetary boundaries and biogeochemical cycles.
    - *Phase archetypes (life and adaptive cycles)*: awareness of systemic phases supports alignment with sustainability goals and long-term resilience.

Summary:

- **Phases** embody *distinctive systemic behaviors and functions* (exploration, structuring, optimization, release, renewal).
- **Cycles** provide the *recurrence and feedback rhythms* that connect phases across time and scale.
- **Integrative archetypes** demonstrate how recurrence and progression interrelate, ensuring engineering practice remains coherent with both internal system dynamics and external contexts.

Purpose and the Capability of Systems

- Lead Author:
- Gary Smith

-

This article is part of the The Nature of Systems area (KA).

Acknowledgement

This article reflects established knowledge from systems science and systems engineering, organized and collated for the SEBoK. Drafting support was provided by OpenAI's ChatGPT, with all content reviewed and finalized by the author, who retains full responsibility.

Framing and Definitions

This article is part of the *Systems Science* knowledge area (KA). **Purpose and capabilities** are fundamental concepts of Function. They complement the **Form-focused concepts** of identity, togetherness, behaviour, and dynamics, as well as the temporal Function concepts of cycles and phases. Together, they describe *why* systems act and *how* they are able to do so.

- **Purpose** refers to the orienting role of systems: the goals, aims, or ends toward which system activity is directed. Purpose may be:
  - **Designed —** explicitly specified in engineered systems.
  - **Emergent —** arising through natural processes of selection or self-organization.
  - **Interpreted —** attributed in social or human systems through meaning-making.
- **Capabilities** refer to the enabling means through which systems realize their purpose. They express what a system can do, its functions, mechanisms, resources, and potentials, and provide the operational foundation for achieving outcomes.

Several perspectives illustrate the breadth of these concepts:

- *"Behaviour, purpose, and teleology are fundamental ways of classifying systems."* — (Rosenblueth, Wiener, Bigelow 1943)
- *"Every living system contains subsystems that carry out the functions of reproducer, decider, and transducer — purposeful subsystems enabling system survival."* — (Miller 1995)
- *"The purpose of a system is what it does (POSIWID)."* — (Beer 1984)

Position in the Fit–Form–Function Framework:

- **Form concepts** describe what a system *is*: its identity, cohesion, and patterns of structure and dynamics. Purpose builds on this foundation by orienting those structures and behaviours toward outcomes, while capabilities arise from the behaviours and dynamics that give Form its power to act.
- **Function concepts** describe what a system *does*. Within Function, **purpose provides orientation** (the "why"), while **capabilities provide potential and means** (the "how").
- **Fit concepts** (value and qualities, addressed in subsequent articles) describe how well a system's purposes and capabilities align with contextual needs, constraints, and expectations.

Taken together, purpose and capabilities define the **directed activity of systems**, distinguishing them from passive structures or random processes and preparing the ground for evaluating their value in context

Introduction: Why Purpose and Capabilities Matter

Purpose and capabilities are central to understanding the **Function** of systems. **Purpose** expresses the orienting *why* of a system, while **capabilities** provide the enabling *means*. Together, they distinguish systems as agents of directed activity rather than passive aggregates of parts.

- In **natural systems**, purpose often appears as survival, reproduction, or adaptation. Capabilities such as metabolism, sensing, movement, or communication enable these purposes to be realized.
- In **social systems**, purpose may be shared goals, cultural values, or strategic aims. Capabilities include knowledge, organizational structures, and technologies that allow groups to pursue those purposes.
- In **engineered systems**, purpose is typically specified in terms of stakeholder needs and mission objectives. Capabilities are expressed in functional architectures, technologies, and performance criteria that allow the system to meet those objectives.

The relationship between purpose and capability is **dynamic**:

- Purposes may evolve or shift as systems interact with their environment.
- Capabilities may expand, degrade, or be repurposed over a system's lifecycle.
- Misalignment between declared purpose and actual capabilities is a frequent cause of system failure.

Examples across domains illustrate the universality of these concepts:

- **Biology**: organisms exhibit purposeful behaviour (survival, reproduction) supported by capabilities such as immune response or sensory-motor coordination.
- **Organizations**: enterprises define strategic purposes (profit, service, sustainability) and build capabilities such as supply chains, human resources, and digital infrastructure.
- **Engineering practice**: the systems engineering process begins with defining purpose (requirements, mission needs) and proceeds through developing and validating capabilities that fulfil that purpose.

Recognizing purpose and capabilities is thus essential for:

1. Describing what systems are *for* and means how they achieve it.
2. Identifying failure modes when purposes and capabilities diverge.
3. Designing coherent engineered systems that align means with ends.

Connection to Fit and Form:

- Purpose and capabilities build on **Form** concepts, identity, togetherness, and dynamics, by directing them toward outcomes and enabling effective action.
- They also prepare the ground for **Fit**, since the value of purposes and the adequacy of capabilities are judged by their qualities in context.
- By focusing on these twin concepts, systemists and practitioners can better understand how systems generate directed outcomes, adapt to change, and fulfill their role within larger contexts.

Frameworks Addressing Purpose and Capabilities

Purpose and capabilities have been treated in multiple systemic traditions, each emphasizing different aspects of **Function**. Together, these frameworks show how the two concepts provide a foundation for understanding and designing systems.

- **General System Theory (GST) (**Bertalanffy 1968) identified *teleology* (goal-directedness) as a central feature of living systems. He argued that systems are distinguished by their tendency to maintain and pursue states in relation to their environment. Here, **identity and dynamics (Form)** are oriented toward continuity and survival through purposeful activity.
- **Cybernetics and Control Theory (**Rosenblueth, Wiener, and Bigelow 1943) distinguished purposeful from non-purposeful behaviour, linking purpose to feedback and control. Cybernetic systems exhibit *goal-seeking*

through regulation and adaptation, showing how **capabilities emerge from system behaviours (Form)** and become directed toward intended outcomes.

- **Miller's Living Systems Theory (LST) (**Miller 1995) described 20 critical subsystems in living systems, including purposeful ones such as the *decider*, and capability-enabling ones such as *input/output transducers*, *reproducers*, and *regulators*. These purposeful and capability subsystems connect **togetherness and dynamics (Form)** with directed systemic Function.
- **Stafford Beer's Viable System Model (VSM) (**Beer 1984) emphasized *viability* as the ultimate purpose of organizations. Capabilities are distributed across recursive levels of management and operations, with systemic purpose emerging from coherent interactions across levels. VSM illustrates how **system purpose and distributed capabilities** must align to maintain Fit within a changing environment.
- **Management Science and Enterprise Models** Purpose is expressed in vision, strategy, and goals, while enterprise capabilities are catalogued and measured through maturity models and frameworks (e.g., Capability Maturity Model Integration, CMMI). These frameworks make explicit the connection between **declared purpose and institutional capabilities**, while increasingly assessing them through *qualities* such as maturity, agility, or resilience.
- **Systems Engineering Practice** In engineered systems, purpose is made explicit through mission statements, stakeholder needs, and requirements. Capabilities are defined in functional architectures, operational concepts (CONOPS), and performance parameters. Modern practice increasingly emphasizes *capability engineering* (e.g., DoDAF, MODAF, NATO Architecture Frameworks), where systems are designed to deliver capabilities that enable mission purposes. Here, the transition to **Fit** becomes clear: capabilities are judged by their *qualities* (e.g., performance, reliability, safety, adaptability) in meeting stakeholder value.

Shared Insight:

Across these traditions, a common pattern emerges: **purpose provides orientation, capabilities provide means, and both must remain aligned for systems to function effectively**. Misalignment leads to inefficiency, fragility, or failure, while coherence supports viability and resilience.

Integrative Perspectives

Across the sciences and systems traditions, **purpose and capabilities are best understood as dual aspects of Function**. Purpose defines *orientation*, the direction or aim of a system's activity, while capabilities define *potential*, the means and capacities that allow that purpose to be realized.

Purpose and Capability as Complementary

- **Purpose without capability** is aspirational but unrealized.
- **Capability without purpose** is unfocused or misapplied.
- **Coherence** arises when purpose and capability are aligned, allowing systems to achieve meaningful outcomes within their context.

Emergence and Scale

- **Purpose** often emerges at higher levels of organization (e.g., the purpose of an organ derives from its role within the body; the purpose of a subsystem derives from its role in the system).
- **Capabilities** are typically instantiated at lower levels (e.g., the cells of the organ provide metabolic and functional capacity).
- Together, this creates a **holarchic relationship**: higher-level purposes guide, while lower-level capabilities enable.

Relational Holon Perspective

From the relational holon viewpoint (Blockley 2025), purpose and capability can be situated in reciprocal quadrants of system activity:

- **Purpose** is associated with reflective and orienting aspects, the capacity to define direction, value, or intent.
- **Capabilities** are associated with realization and action, the capacity to enact, regulate, and sustain system functioning.
- The **cycle of praxis** connects the two: purpose shapes the design and mobilization of capabilities, while capabilities constrain and inform the evolution of purpose.

Systemic Integration

- In **natural systems**, purposes like survival or reproduction are coupled with capabilities such as metabolism, reproduction, and adaptation.
- In **social systems**, collective purposes (e.g., justice, prosperity) are pursued through cultural, institutional, and technological capabilities.
- In **engineered systems**, explicitly declared purposes (e.g., mission needs) are realized through designed capabilities (e.g., functions, performance characteristics).

In summary, purpose and capabilities are **integrative systemic concepts**. They represent the ongoing dialogue between *ends and means*, *orientation and potential*, *why and how*. Their coherence is foundational to the viability and effectiveness of all systems, natural or artificial.

Bridge to Fit: The adequacy of capabilities, and the legitimacy of purposes, are ultimately judged by their **qualities in context**, a theme taken up in the subsequent article on *Value and Qualities of Systems*.

Archetypes of Purpose and Capability

Purpose and capabilities manifest in recurring **archetypes**, systemic patterns that appear across natural, social, and engineered systems. These archetypes make the abstract concepts of purpose and capability tangible and provide useful analogies for systems engineering practice.

Purpose Archetypes

Systems exhibit a range of orienting purposes, from basic survival to transcendent aims. Common archetypes include:

- **Survival –** maintaining existence within an environment.
  - *Examples*: cellular repair in biology; safety-critical functions in engineered systems.
- **Growth and Expansion –** increasing scale, influence, or resources.
  - *Examples*: ecological succession; market expansion in enterprises.
- **Coherence and Stability –** maintaining balance, efficiency, or systemic order.
  - *Examples*: homeostasis in organisms; redundancy and stability measures in engineered systems.
- **Adaptation and Resilience –** adjusting purpose in response to change.
  - *Examples*: species adaptation; organizational pivot strategies.
- **Transcendence –** pursuing goals beyond immediate survival or efficiency.
  - *Examples*: evolution of consciousness; societal aims such as justice or sustainability.

Capability Archetypes

Capabilities are the systemic means by which purposes are enacted. Recurrent capability archetypes include:

- **Sensing –** perceiving and gathering information.
  - *Examples*: sensory organs in animals; sensors in cyber-physical systems.
  - *Miller's Living Systems*: Input transducer subsystem.
- **Processing –** interpreting, evaluating, or deciding.
  - *Examples*: neural processing in organisms; decision-support systems in enterprises.
  - *Miller's Living Systems*: Decider subsystem.

- **Acting –** effecting change through energy or force.
  - *Examples*: muscular movement; actuators in machines.
  - *Miller's Living Systems*: Effector subsystem.
- **Communicating –** transmitting signals or coordinating with others.
  - *Examples*: language in humans; network protocols in ICT systems.
  - *Miller's Living Systems*: Internal and external transducers.
- **Adapting –** modifying structure or behaviour to sustain viability.
  - *Examples*: genetic mutation and learning; adaptive control in engineering.
  - *Miller's Living Systems*: Reproducer subsystem.

Integrative Archetypes

Some archetypes combine both purpose and capability, illustrating their interdependence:

- **Adaptive Capacity –** the capability to change purpose in response to context.
- **Purposeful Orientation –** the alignment of multiple capabilities around a shared purpose.
- **Viability –** the systemic capacity to sustain purpose through distributed capabilities across scales (Beer's VSM).

Together, these archetypes show that purpose provides orientation (the "why"), capabilities provide potential (the means "how"), and their integration enables systems to thrive, adapt, and innovate. The qualities of capabilities, such as reliability, resilience, or efficiency, determine whether these archetypes achieve Fit within their context

Implications for Systems Engineering

Purpose and capabilities are central to systems engineering practice. They underpin requirements definition, architecture, verification, and lifecycle management. Recognizing their archetypes helps engineers design systems that are both coherent and viable.

Defining System Purpose

- In SE, purpose is captured in **stakeholder needs, mission statements, and requirements**.
- Purpose archetypes guide orientation: survival (safety), growth (scalability), stability (coherence), adaptation (resilience), or transcendence (sustainability, societal goals).
- A clear statement of purpose provides the orienting "north star" for design and development.

Engineering for Capabilities

- Systems are realized through **capabilities** defined in functional architectures and operational concepts (CONOPS).
- Capability archetypes translate into practice: sensing (data collection), processing (control logic), acting (effectors), communicating (interfaces), and adapting (reconfiguration).
- Capability engineering frameworks (e.g., DoDAF, MODAF, NATO) formalize this process by defining what a system must be able to do before specifying how it will do it.

Alignment of Purpose and Capabilities

- **Alignment is critical**: declared purpose must be achievable by available capabilities.
- Misalignment leads to:
  - *Overreach* — purposes declared without sufficient enabling capabilities.
  - *Drift* — capabilities developed without serving the core purpose.
- Successful alignment enables coherence, stakeholder confidence, and operational success.

Lifecycle Dynamics

- **Purposes evolve** over time as needs and environments change.
- **Capabilities degrade, adapt, or expand** as systems are sustained, upgraded, or reconfigured.

- Engineers must anticipate these dynamics by designing adaptive architectures and sustainment strategies that preserve alignment.

Enterprise and System-of-Systems (SoS) Contexts

- At enterprise and SoS levels, purposes are often plural, reflecting diverse stakeholders.
- Capabilities must therefore be **modular, interoperable, and scalable**, enabling systems to serve multiple or shifting purposes.
- Nested and coupled cycle archetypes (from earlier articles) highlight the importance of coordinating purposes and capabilities across levels.

Risk, Resilience, and Sustainability

- **Risk** arises when critical purposes depend on fragile or narrowly defined capabilities.
- **Resilience** requires redundant or adaptive capabilities to sustain purpose through disruption.
- **Sustainability** demands that engineered purposes and capabilities remain coherent with ecological and societal contexts over the long term

Summary

Purpose and capabilities are twin pillars of Function. Purpose provides orientation, the *why* of a system. Capabilities provide potential, the *how* through which purposes are realized. Together, they distinguish systems as directed, effective entities rather than passive aggregates of parts.

Key insights include:

- Purpose can be **designed** (engineered), **emergent** (natural), or **interpreted** (social).
- Capabilities encompass **sensing, processing, acting, communicating, and adapting**, and can be mapped to purposeful subsystems identified in systems science (e.g., Miller's Living Systems Theory).
- Archetypes of purpose (survival, growth, coherence, adaptation, transcendence) and capability (sensing, processing, acting, communicating, adapting) provide recurring patterns that guide analysis and design.
- Integrative archetypes, such as adaptive capacity, purposeful orientation, and viability, illustrate the interdependence of ends and means.
- Misalignment between purpose and capability is a frequent source of system fragility, while coherence supports resilience and sustainability.

Connection to Form: Purpose builds on the identity and togetherness of systems, orienting their behaviours and dynamics toward directed outcomes. Capabilities arise from these dynamics, providing the means by which systems act.

Connection to Function-in-time: Cycles and phases describe how systems progress and recur through time. Purpose and capabilities define *what those temporal processes are for* and *how they are enabled*.

Connection to Fit: The adequacy of purposes and the effectiveness of capabilities are ultimately judged by their **qualities in context**, such as reliability, adaptability, efficiency, and sustainability. These qualities determine whether systems are truly fit for purpose within their environment.

By clarifying purpose and capabilities, this article establishes a foundation for understanding the **directed activity of systems**, while preparing the way for the next article in this series: *The Value and Qualities of Systems*.

Value and the Quality of Systems

- Lead Author:
- Gary Smith

-

Acknowledgement

This article reflects established knowledge from systems science and systems engineering, organized and collated for the SEBoK. Drafting support was provided by OpenAI's ChatGPT, with all content reviewed and finalized by the author, who retains full responsibility.

Framing and Definitions

This article is part of the *Nature of Systems* knowledge area (KA). It addresses two essential concepts within the **Fit** dimension of the Fit–Form–Function (FFF) triad:

- **Value** refers to the contextual significance or worth of a system, judged relative to stakeholder goals, ecological constraints, or societal purposes.
- **Qualities** are the attributes through which a system's capabilities are expressed and evaluated, such as reliability, resilience, elegance, or sustainability.

In this framing:

- **Form** describes what a system is.
- **Function** describes what a system does.
- **Fit** describes how well a system aligns with its environment and purpose.

> "The quality of a system is the degree to which it satisfies the stated and implied needs of its various stakeholders."
>
> — (ISO/IEC 25010 2011)
>
> "The purpose of a system is what it does (POSIWID)… but how well it does it determines its viability."
>
> — (Beer 1984)
>
> "Stability, equilibrium, and regulation are universal qualities observed across natural systems."
>
> — (Troncale 1978)

Introduction: Why Value and Qualities Matter

Systems engineering often emphasizes purpose and capability, what systems are for and how they perform. However, to determine whether a system is **fit for purpose**, we must evaluate both:

- **Qualities**: How well are capabilities expressed?
- **Value**: Why does it matter in a given context?

These evaluations are **relational and dynamic**:

- In **natural systems**, qualities such as resilience and redundancy determine survival value.
- In **social systems**, value is framed by cultural, ethical, and institutional goals.
- In **engineered systems**, system qualities drive stakeholder satisfaction, mission success, and lifecycle viability.

As contexts evolve, the relative value of qualities may change. For example, climate adaptation shifts emphasis toward sustainability and resilience, qualities once subordinate to efficiency or cost.

Recognizing these shifting balances is essential for:

- Prioritizing system requirements

- Managing trade-offs among qualities
- Ensuring long-term value beyond immediate utility

Frameworks Addressing Value and Qualities

A range of systemic and engineering traditions address Fit through either value, qualities, or both:

Framework	Key Contribution
General Systems Theory (GST)	Emergent system properties, adaptability, coherence, robustness, inform evaluation (Bertalanffy 1968).
Troncale's System Isomorphies	Recurring qualities like equilibrium and regulation appear across domains (Troncale 1978).
Living Systems Theory	Viability arises from subsystem qualities like throughput, redundancy, and integrity (Miller 1995).
Cybernetics	Control qualities such as feedback responsiveness and robustness determine system effectiveness (Wiener 2019; Ashby 1956).
Viable System Model (VSM)	Organizational viability is tied to variety-handling and recursive regulation (Beer 1984).
INCOSE & ISO Standards	Codify measurable system qualities such as reliability, usability, and sustainability (ISO/IEC 25010; INCOSE SE Handbook 2023).
Management Science	Value is modeled through performance metrics, stakeholder satisfaction, and systemic contribution (Ackoff 1971; Checkland 1999).

Each tradition affirms that qualities shape performance, while value determines contextual worth.

Integrative Perspectives

Value and Qualities as Dual Aspects of Fit

- **Value without qualities** is abstract, a claim without demonstration.
- **Qualities without value** are technical features without systemic relevance.

Together, they form the lens of Fit: **value asks "why it matters"; qualities show "how well" it is achieved.**

Emergence and Scale

- **Qualities** emerge from interactions between Form and Function.
- **Value** emerges in relation to systems of reference, stakeholders, environments, ecosystems, or societal structures.

This dual emergence implies that **Fit is always contextual and multi-level**.

Relational Holon Perspective

Building on Blockley (2025), the **relational holon** offers a dynamic view:

- **Qualities** correspond to the realization and actualization quadrants, how the system enacts itself.
- **Value** arises in the reflective and orienting quadrants, where meaning, ethics, and purpose emerge.

Archetypes of Value and Qualities

Value and qualities manifest in recurring evaluative patterns across domains.

Value Archetypes

Archetype	Description	Example
Utility	Direct usefulness	A solar panel's energy output
Exchange	Interoperability or trade	API compatibility
Intrinsic Worth	Independent significance	Biodiversity, cultural assets
Systemic Contribution	Enables higher-level functionality	Keystone species; transport infrastructure
Transformative Value	Enables paradigm shifts	AI systems; emergence of consciousness

Quality Archetypes

Archetype	Description	Example
Reliability	Consistent performance	Fault-tolerant hardware
Resilience	Recovery from disturbance	Forest regrowth; network redundancy
Adaptability	Reconfiguration under change	Agile organizations; evolutionary traits
Efficiency	Resource-performance ratio	Metabolic pathways; lean manufacturing
Sustainability	Long-term endurance in context	Closed-loop cycles; circular economy

Integrative Archetypes

Archetype	Description
Fitness for Purpose	Adequate qualities aligned with intent
Systemic Elegance	Simplicity, sufficiency, and coherence
Alignment with Context	Harmonization with ecological, societal, or stakeholder realities

Implications for Systems Engineering

Defining Value

Value in SE spans:

- **Operational utility** (mission success)
- **Stakeholder satisfaction** (usability, safety)
- **Long-term contribution** (sustainability, resilience)

Value archetypes help clarify these distinctions and link design choices to contextual relevance.

Engineering for Qualities

System qualities are:

- **Specified** as non-functional requirements
- **Assessed** through verification, validation, and model-based methods
- **Balanced** through trade-off analysis

Standards such as ISO/IEC 25010 and 15288 offer a structured vocabulary for evaluating qualities.

(Rousseau 2019) proposes *systemic virtues,* such as coherence, elegance, and resilience, as foundational qualities that link system design to broader systemic contribution and aesthetic value, offering a promising bridge between engineering practice and systems science.

Trade-offs and Lifecycle Change

- Systemic trade-offs (e.g., performance vs. maintainability) must be stakeholder-informed and lifecycle-aware.
- Both **qualities and perceived value change over time**, necessitating re-evaluation across design, operation, and decommissioning.

System-of-Systems and Enterprise Engineering

- Large-scale systems require balancing diverse and sometimes conflicting stakeholder values.
- Enterprise architecture, value network analysis, and resilience engineering help navigate this complexity.

Sustainability and Planetary Fit

Systems that harm ecological integrity lose long-term value, regardless of short-term utility. SE must increasingly:

- Address **planetary boundaries** (Rockström et al. 2009)
- Align value models with **ecosystem services**
- Adopt **circularity** and **regenerative design** principles

Summary

Value and qualities form the evaluative backbone of the *Fit* dimension in systems thinking:

- **Value** is contextual significance—why a system matters to stakeholders, ecosystems, or society.
- **Qualities** describe how well a system performs across dimensions like reliability, adaptability, and sustainability.
- **Together**, they determine whether a system is truly fit for its environment and purpose, not only in theory but across its lifecycle and across scales.

This article completes the transition from what systems are (*Form*) and do (*Function*) to how they are judged (*Fit*). The next article, *Consciousness and the Experience of Systems*, extends this evaluation into perceptual and experiential dimensions.

This article reflects established knowledge from systems science and systems engineering, organized and collated for the SEBoK. Drafting support was provided by OpenAI's ChatGPT, with all content reviewed and finalized by the lead author, who retains full responsibility.

Framing and Definitions

This article is part of the "Nature of Systems" knowledge area. Experience and consciousness are foundational concepts in the Fit dimension, complementing the Form-oriented concepts of identity, togetherness, behavior, and dynamics, and the Function-oriented concepts of cycles, phases, purpose, and capabilities. These two concepts describe how systems participate in and make sense of their environments.

- **Experience** is how a system encounters, senses, and responds to its environment. All systems experience the world to some degree, but complexity increases the richness and nuance of this encounter.
- **Consciousness** is the integration of experience into awareness. It ranges from basic responsiveness in physical systems to reflective, intentional cognition in higher-order systems.

These concepts reflect the shift from describing systems mechanistically to understanding them as participants in a relational, evolving whole.

> "Living systems are cognitive systems, and living as a process is a process of cognition." — (Maturana & Varela 1980)
>
> "Anticipatory systems contain models of themselves and their environment, enabling them to act in present terms for future states." — (Rosen 1985)
>
> "All conscious systems share the capacity to integrate information across a whole, though in differing degrees." — (Tononi 2004)
>
> "Consciousness can be understood at multiple levels, with richer forms emerging with greater systemic complexity." — (Jonkisz 2016)

Position in the Fit–Form–Function Framework:.

Experience and consciousness are the apex Fit concepts. They govern how systems interpret qualities, ascribe value, and evolve in relation to their context.

Introduction: Why Experience and Consciousness Matter

Experience and consciousness clarify how systems live in, sense, and adapt to their context. While typically associated with human cognition, these concepts generalize to all systems as properties that scale with complexity.

- **Physical systems** experience interaction through forces and energy exchanges.
- **Biological systems** sense, perceive, and adapt.
- **Social systems** create shared meaning, culture, and governance.
- **Engineered systems** increasingly require attention to user experience, AI autonomy, and situational awareness.

These concepts help bridge:

- **Qualities** (how well a system performs)
- **Value** (why it matters in a context)
- **Experience** (how systems encounter context)
- **Consciousness** (how systems interpret and act on this encounter)

Understanding experience and consciousness allows engineers to design systems that support trust, ethical behavior, and long-term sustainability.

Frameworks Addressing Experience and Consciousness

A variety of traditions offer perspectives on how systems experience and integrate awareness.

Philosophical Traditions

- **Phenomenology** (Husserl, Merleau-Ponty 1931): focuses on lived experience as the foundation of meaning.
- **Mind-body problem & qualia**: address whether consciousness is reducible or emergent.
- **subjective experience:** (Chalmers 1996) consciousness poses a "hard problem" of .

Neuroscience and Cognitive Science

- **Integrated Information Theory (IIT)** (Tononi 2004, 2012): consciousness correlates with the degree of integrated information (Phi).
- **Global Workspace Theory** (Baars 1988): models consciousness as information broadcast across subsystems.
- **Predictive Processing** (Friston 2010): consciousness emerges from prediction-error minimization.

Systems Science

- **Autopoiesis** (Maturana & Varela 1980): living systems produce and regulate themselves; cognition is intrinsic.
- **Anticipatory Systems** (Rosen 1985): consciousness is modeled as the ability to simulate future outcomes.
- **Relational Holon** (Blockley, Smith 2025): integrates system, context, and reflection.
- **Levels of consciousness:** (Jonkisz 2015): presents a graded model of consciousness across system complexity.

Engineering and Applied Frameworks

- **HSI and UX Design**: ensure that human users experience systems meaningfully and safely.
- **Autonomy levels** (e.g., SAE J3016): imply degrees of system situational awareness.
- **AI systems**: simulate perceptual and reflective capabilities without full consciousness.

Integrative Perspectives

Experience and consciousness are deeply interconnected:

- **Experience** is the encounter with environment.
- **Consciousness** is the integration and interpretation of that experience.

Their **systemic coherence** arises from:

- **Complementarity**: One grounds the other; both are needed.
- **Scaling**: All systems experience; more complex systems develop reflective awareness.
- **Holonic integration**: Systems exist within wholes, and consciousness links individual and collective perspectives.

In the **relational holon model** (Blockey, Smith 2025):

- Experience corresponds to engagement at the system-context boundary.
- Consciousness arises in the reflective and orienting quadrants.
- The cycle of praxis connects sensory input, integration, interpretation, and action.

This model bridges:

- **Natural systems** (perception, survival)
- **Social systems** (shared meaning, culture)
- **Engineered systems** (human interaction, AI autonomy)

Archetypes of Experience and Consciousness

These archetypes clarify how systems *participate* in context, and how richer systems *perceive and integrate* meaning.

Experience Archetypes	Description	Example Systems
Sensation	Direct encounter with stimuli	Sensors, immune cells, physical particles
Perception	Organizing and interpreting input	Animals, pattern recognition systems
Emotion/Affect	Valenced evaluation of experience	Human response, social trust mechanisms
Interaction	Reciprocal engagement with environment	Ecosystems, conversational agents

Consciousness Archetypes	Description	Example Systems
Awareness	Capacity to register and respond	Drivers, pilots, automated vehicles
Self-reflection	Awareness of internal state	Humans, adaptive monitoring tools
Intentionality	Goal-directed awareness	Strategic planners, autonomous agents
Collective consciousness	Shared awareness among agents	Cultures, swarm intelligence, organizations

Integrative Archetypes:

- **Anticipatory capacity**: (Rosen 1985)
- **Autopoietic cognition**: (Maturana, Varela 1980)
- **Relational reflexivity**: (Blockley, Smith 2025)

These demonstrate how experience and consciousness scale from system structure to meaningful participation.

Implications for Systems Engineering

Experience and consciousness may appear abstract, but they have direct implications for systems engineering. Engineers increasingly design systems that shape human experience, simulate conscious-like properties, or participate in collective decision processes. Addressing these concepts ensures that engineered systems remain **fit for purpose, trustworthy, and sustainable**.

Area	Implication
Human-System Integration	Design must account for human perception, trust, interpretation, and cognitive load.
Autonomy and AI	AI systems simulate conscious-like behavior (awareness, modeling, adaptation).
Ethical Design	Systems affect lived experience and require consideration of dignity, fairness, and responsibility.
Collective Systems	Organizational awareness and decision-making must align with shared meaning and goals.
Lifecycle Integration	Experience accumulates; consciousness-like properties must be embedded in adaptive feedback loops.

Systems engineering increasingly operates in domains where:

- **User experience** shapes effectiveness.
- **Trust** is essential for adoption.
- **Autonomous systems** interact with uncertain environments.

This makes experience and consciousness not optional curiosities, but core design and lifecycle concerns.

Summary

Experience and **consciousness** are the capstone concepts in the **Fit** dimension of systems. They represent how systems *participate in*, *perceive*, and *integrate meaning* from their environment.

Key insights:

- **Experience** is universal: all systems are affected by and interact with their environment. The *richness* of experience scales with complexity.
- **Consciousness** is the integration of experience into *awareness*. It includes responsiveness, anticipation, self-reflection, and intentionality.
- **Archetypes** of experience (sensation, perception, emotion, interaction) and consciousness (awareness, self-reflection, collective meaning) recur across physical, biological, social, and engineered systems.
- **Integrative concepts** such as **anticipation**, **autopoietic cognition**, and **relational reflexivity** demonstrate how experience and consciousness deepen system Fit.
- These properties underpin emerging concerns in **AI, ethics, human–system integration**, and **systemic responsibility**.

By clarifying experience and consciousness as properties of all systems, scaling with complexity from simple responsiveness to reflective awareness, we affirm that systems are participants in the greater whole. This recognition strengthens the bridge between systems science and systems engineering, ensuring that practice attends not only to technical performance but also to **meaning, trust, and responsible participation in life's unfolding system of systems.**

This knowledge area (KA) provides a guide to some of the major developments in systems science, which is an interdisciplinary field of science that studies the nature of complex systems in nature, society, and engineering.

This is part of the wider systems knowledge which can help to provide a common language and intellectual foundation, and make practical systems concepts, principles, patterns and tools accessible to systems engineering (SE) as discussed in the Introduction to Part 2.

Topics

Each part of the SEBoK is divided into KAs, which are groupings of information with a related theme. The KAs, in turn, are divided into topics. This KA contains the following topics:

- History of Systems Science
- The origins of Systems Approaches
- Complexity
- Emergence

Introduction

Systems science brings together research into all aspects of systems with the goal of identifying, exploring, and understanding patterns of complexity and emergence which cross disciplinary fields and areas of application. It seeks to develop interdisciplinary foundations which can form the basis of theories applicable to all types of systems, independent of element type or application; additionally, it could form the foundations of a meta-discipline unifying traditional scientific specialisms.

The History of Systems Science article describes some of the important multidisciplinary fields of research of which systems science is composed.

A second article presents and contrasts the underlying theories and origins behind some of the classic system approaches taken in applying systems science to real problems.

People who think and act in a systems way are essential to the success of both research and practice. Successful systems research will not only apply systems thinking to the topic being researched but should also consider a systems thinking approach to the way the research is planned and conducted. It would also be of benefit to have

people involved in research who have, at a minimum, an awareness of system practice and ideally are involved in practical applications of the theories they develop.

- Scott Jackson, Janet Singer, and Duane Hybertson

-

This article is part of the Systems Science knowledge area (KA). It describes some of the important multidisciplinary fields of research comprising systems science in historical context.

Systems science is an integrative discipline which brings together ideas from a wide range of sources which share a common systems theme. Some fundamental concepts now used in systems science have been present in other disciplines for many centuries, while equally fundamental concepts have independently emerged as recently as 40 years ago (Flood and Carson 1993).

The “Systems Problem”

Questions about the nature of systems, organization, and complexity are not specific to the modern age. As International Council on Systems Engineering (INCOSE) pioneer and former International Society for System Sciences (ISSS) President John Warfield put it, “Virtually every important concept that backs up the key ideas emergent in systems literature is found in ancient literature and in the centuries that follow.” (Warfield 2006.) It was not until around the middle of the 20th Century, however, that there was a growing sense of a need for, and possibility of a scientific approach to problems of organization and complexity in a “science of systems” per se.

The explosion of knowledge in the natural and physical sciences during the 18th and 19th centuries had made the creation of specialist disciplines inevitable: in order for science to advance, there was a need for scientists to become expert in a narrow field of study. The creation of educational structures to pass on this knowledge to the next generation of specialists perpetuated the fragmentation of knowledge (M’Pherson 1973).

This increasing specialization of knowledge and education proved to be a strength rather than a weakness for problems which were suited to the prevailing scientific methods of experimental isolation and analytic reduction. However, there were areas of both basic and applied science that were not adequately served by those methods alone. The systems movement has its roots in two such areas of science: the biological-social sciences, and a mathematical-managerial base stemming first from cybernetics and operations research, and later from organizational theory.

Biologist Ludwig von Bertalanffy was one of the first to argue for and develop a broadly applicable scientific research approach based on **Open System Theory** (Bertalanffy 1950). He explained the scientific need for systems research in terms of the limitations of analytical procedures in science.

These limitations, often expressed as emergent evolution or "the whole is more than a sum of its parts," are based on the idea that an entity can be resolved into and reconstituted from its parts, either material or conceptual:

> *This is the basic principle of "classical" science, which can be circumscribed in different ways: resolution into isolable causal trains or seeking for "atomic" units in the various fields of science, etc.*

He stated that while the progress of "classical" science has shown that these principles, first enunciated by Galileo and Descartes, are highly successful in a wide realm of phenomena, but two conditions are required for these principles to apply:

> *The first is that interactions between "parts" be non-existent or weak enough to be neglected for certain research purposes. Only under this condition, can the parts be "worked out," actually, logically, and mathematically, and then be "put together." The second condition is that the relations describing the behavior of parts be linear; only then is the condition of summativity given, i.e., an equation describing the behavior of the total is of the same form as the equations describing the behavior of the parts.*
>
> *These conditions are not fulfilled in the entities called systems, i.e. consisting of parts "in interaction" and description by nonlinear mathematics. These system entities describe many real world situations: populations, eco systems, organizations and complex man made technologies. The methodological problem of systems theory is to provide for problems beyond the analytical-summative ones of classical science.* (Bertalanffy 1968, 18-19)

Bertalanffy also cited a similar argument by mathematician and co-founder of information theory Warren Weaver in a 1948 American Scientist article on “Science and Complexity.” Weaver had served as Chief of the Applied Mathematics Panel at the U.S. Office of Scientific Research and Development during WWII. Based on those experiences, he proposed an agenda for what he termed a new “science of problems of organized complexity.”

Weaver explained how the mathematical methods which had led to great successes of science to date were limited to problems where appropriate simplifying assumptions could be made. What he termed “problems of simplicity” could be adequately addressed by the mathematics of mechanics, while “problems of disorganized complexity” could be successfully addressed by the mathematics of statistical mechanics. But with other problems, making the simplifying assumptions in order to use the methods would not lead to helpful solutions. Weaver placed in this category problems such as, *how the genetic constitution of an organism expresses itself in the characteristics of the adult*, and *to what extent it is safe to rely on the free interplay of market forces if one wants to avoid wide swings from prosperity to depression*. He noted that these were complex problems which involved “analyzing systems which are organic wholes, with their parts in close interrelation.”

> *These problems-and a wide range of similar problems in the biological, medical, psychological, economic, and political sciences-are just too complicated to yield to the old nineteenth century techniques which were so dramatically successful on two-, three-, or four-variable problems of simplicity. These new problems, moreover, cannot be handled with the statistical techniques so effective in describing average behavior in problems of disorganized complexity [problems with elements exhibiting random or unpredictable behavior].*

These new critical global problems require science to make a third great advance,

> *An advance that must be even greater than the nineteenth-century conquest of problems of simplicity or the twentieth-century victory over problems of disorganized complexity. Science must, over the next 50 years, learn to deal with these problems of organized complexity [problems for which complexity "emerges" from the coordinated interaction between its parts].* (Weaver 1948.)

Weaver identified two grounds for optimism in taking on this great challenge: 1.) developments in mathematical modeling and digital simulation, and 2.) the success during WWII of the "mixed team" approach of operations analysis, where individuals from across disciplines brought their skills and insights together to solve critical, complex problems.

The importance of modeling and simulation and the importance of working across disciplinary boundaries have been the key recurring themes in development of this "third way" science for systems problems of organized complexity.

The Development of Systems Research

The following overview of the evolution of systems science is broadly chronological, but also follows the evolution of different paradigms in system theory.

Open Systems and General Systems Theory

General system theory (GST) attempts to formulate principles relevant to all open systems (Bertalanffy 1968). GST is based on the idea that correspondence relationships (homologies) exist between systems from different disciplines. Thus, knowledge about one system should allow us to reason about other systems. Many of the generic system concepts come from the investigation of GST.

In 1954, Bertalanffy co-founded, along with Kenneth Boulding (economist), Ralph Gerard (physiologist) and Anatol Rapoport (mathematician), the Society for General System Theory (renamed in 1956 to the Society for General Systems Research, and in 1988 to the International Society for the Systems Sciences).

The initial purpose of the society was "to *encourage the development of theoretical systems which are applicable to more than one of the traditional departments of knowledge ... and promote the unity of science through improving the communication among specialists*." (Bertalanffy 1968.)

This group is considered by many to be the founders of **System Age Thinking** (Flood 1999).

Cybernetics

Cybernetics was defined by Wiener, Ashby and others as the study and modeling of communication, regulation, and control in systems (Ashby 1956; Wiener 1948). Cybernetics studies the flow of information through a system and how information is used by the system to control itself through feedback mechanisms. Early work in cybernetics in the 1940s was applied to electronic and mechanical networks, and was one of the disciplines used in the formation of early systems theory. It has since been used as a set of founding principles for all of the significant system disciplines.

Some of the key concepts of feedback and control from Cybernetics are expanded in the Concepts of Systems Thinking article.

Operations Research

Operations Research (OR) considers the use of technology by an organization. It is based on the use of mathematical modeling and statistical analysis to optimize decisions on the deployment of the resources under an organization's control. An interdisciplinary approach based on scientific methods, OR arose from military planning techniques developed during World War II.

Operations Research and Management Science (ORMS) was formalized in 1950 by Ackoff and Churchman applying the ideas and techniques of OR to organizations and organizational decisions (Churchman et. al. 1950).

Systems Analysis

Systems analysis was developed by RAND Corporation in 1948. It borrowed from and extended OR, including using black boxes and feedback loops from cybernetics to construct block diagrams and flow graphs. In 1961, the Kennedy Administration decreed that systems analysis techniques should be used throughout the government to provide a quantitative basis for broad decision-making problems, combining OR with cost analysis (Ryan 2008).

Systems Dynamics

Systems dynamics (SD) uses some of the ideas of cybernetics to consider the behavior of systems as a whole in their environment. SD was developed by Jay Forrester in the 1960's (Forrester 1961). He was interested in modeling the dynamic behavior of systems such as populations in cities and industrial supply chains. See Systems Approaches for more details.

SD is also used by Senge (1990) in his influential book *The Fifth Discipline*. This book advocates a systems thinking approach to organization and also makes extensive use of SD notions of feedback and control.

Organizational Cybernetics

Stafford Beer was one of the first to take a cybernetics approach to organizations (Beer 1959). For Beer, the techniques of ORMS are best applied in the context of an understanding of the whole system. Beer also developed a **Viable Systems Model** (Beer 1979), which encapsulates the effective organization needed for a system to be viable (to survive and adapt in its environment).

Works in cybernetics and ORMS consider the mechanism for communication and control in complex systems, and particularly in organizations and management sciences. They provide useful approaches for dealing with operational and tactical problems within a system, but do not allow consideration of more strategic organizational problems (Flood 1999).

Hard and Soft Systems Thinking

Action research is an approach, first described by Kurt Lewin, as a reflective process of progressive problem solving in which reflection on action leads to a deeper understanding of what is going on and to further investigation (Lewin 1958).

Peter Checkland's action research program in the 1980's led to an Interpretative-Based Systemic Theory which seeks to understand organizations by not only observing the actions of people, but also by building understandings of the cultural context, intentions and perceptions of the individuals involved. Checkland, himself starting from a systems engineering (SE) perspective, successively observed the problems in applying a SE approach to the more fuzzy, ill-defined problems found in the social and political arenas (Checkland 1978). Thus, he introduced a distinction between hard systems and soft systems - see also Systems Approaches.

Hard systems views of the world are characterized by the ability to define purposes, goals, and missions that can be addressed via engineering methodologies in an attempt to, in some sense, "optimize" a solution.

In hard system approaches, the problems may be complex and difficult but they are known and can be fully expressed by the investigator. Such problems can be solved by selecting from the best available solutions (possibly with some modification or integration to create an optimum solution). In this context, the term "systems" is used to describe real world things; a solution system is selected, created and then deployed to solve the problem.

Soft systems views of the world are characterized by complex, problematical, and often mysterious phenomena for which concrete goals cannot be established and which require learning in order to make improvement. Such systems are not limited to the social and political arenas and also exist within and amongst enterprises where complex, often ill-defined patterns of behavior are observed that are limiting the enterprise's ability to improve.

Soft system approaches reject the idea of a single problem and consider **problematic** situations in which different people will perceive different issues depending upon their own viewpoint and experience. These problematic situations are not solved but managed through interventions which seek to reduce "discomfort" among the participants. The term system is used to describe systems of ideas, conceptual systems which guide our understanding of the situation, or help in the selection of intervention strategies.

These three ideas of “problem vs. problematic situation,” “solution vs. discomfort reduction,” and “the system vs. systems understanding” encapsulate the differences between hard and soft approaches (Flood and Carson 1993).

Critical Systems Thinking

The development of a range of hard and soft methods naturally leads to the question of which method to apply in what circumstances (Jackson 1989). Critical systems thinking (CST), or **critical management science** (Jackson 1985), attempts to deal with this question.

The word **critical** is used in two ways. Firstly, critical thinking considers the limits of knowledge and investigates the limits and assumptions of hard and soft systems, as discussed in the above sections. The second aspect of critical thinking considers the ethical, political and coercive dimension and the role of system thinking in society; see also Systems Approaches.

Service Science and Service Systems Engineering

The world economies have transitioned over the past few decades from manufacturing economies that provide goods, to service based economies. Harry Katzan defined the newly emerging field of service science: "Service science is defined as the application of scientific, engineering, and management competencies that a service-provider organization performs that creates value for the benefit of the client or customer" (Katzan 2008, vii).

The disciplines of service science and service engineering have developed to support this expansion and are built on principles of systems thinking but applied to the development and delivery of service systems.

Service Systems Engineering is described more fully in the Service Systems Engineering KA in Part 4 of the SEBoK.

Systems Approaches

- Lead Author:

- Scott Jackson, Janet Singer, and Duane Hybertson

-

This article is part of the Systems Science knowledge area (KA). It presents issues in the comparison and analysis of classic systems approaches developed by the systems science community. Some of these ideas contribute to basic theory and methods that are used in systems thinking discussed in the Systems Thinking KA.

What is a Systems Approach?

In Bertalanffy's introduction to his 1968 book *General System Theory* (GST), he characterizes a systems approach as:

> *A certain objective is given; to find ways and means for its realization requires the system specialist (or team of specialists) to consider alternative solutions and to choose those promising optimization at maximum efficiency and minimum cost in a tremendously complex network of interactions.* (Bertalanffy 1968, 4)

He goes on to list as possible elements of a systems approach: “classical” systems theory (differential equations), computerization and simulation, compartment theory, set theory, graph theory, net theory, cybernetics, information theory, theory of automata, game theory, decision theory, queuing theory, and models in ordinary language.

This description is similar to what Warren Weaver identified as the methods used successfully by “mixed teams” during World War II (WWII) on “problems of organized complexity”. However, some conditions that had contributed to success during wartime did not hold after the war, such as a clear focus on well-defined common goals that motivated participants to work across disciplinary boundaries.

By the early 1970’s, there was growing disillusionment with the promise that a systems approach would provide easy solutions for all complex problems. There was particular criticism from some, including pioneers of Operations Research and Management Science (ORMS) like Ackoff and Churchman, that reliance on rote mathematical methods to identify optimal solutions among fixed alternatives had become just as inflexible and unimaginative an approach to complex problems as whatever it had replaced. Interest grew in examining and comparing methods and methodologies to better understand what could help ensure the best thinking and learning in terms of systems in systems approaches to practice.

Issues in Systems Approaches

A systems approach is strongly associated with systems thinking and how it helps to guide systems practice. In What is Systems Thinking? the key ideas of considering a system holistically, setting a boundary for a problem/solution of interest, and considering the resulting system-of-interest from outside its boundary are identified (Churchman 1979; Senge 2006).

A systems approach can view a system as a “holon” – an entity that is itself a “whole system” that interacts with a mosaic of other holons in its wider environment (Hybertson 2009), while also being made up of interacting parts. We can use this model recursively – each part of the system may be a system in its own right, and can itself be viewed both as an entity as seen from outside, and as a set of interacting parts. This model also applies in upwards recursion, so the original “system-of-interest” is an interacting part of one or more wider systems.

This means that an important skill in a systems approach is to identify the "natural holons" in the problem situation and solution systems and to make the partitioning of responsibilities match the "natural holons," so as to minimize the coupling between parallel activities when applying a solution. This is the "cohesive/loose coupling" heuristic that has been around for a long time in many design disciplines.

Another consequence of the holistic nature of a systems approach is that it considers not only a problem situation and a solution system but also the system created and deployed to apply one to the other. A systems approach must consider both the boundary of the system of concern as well as the boundary of the system inquiry (or model). Real systems are always open, i.e., they interact with their environment or supersystem(s). On the other hand, real models are always "closed" due to resource constraints — a fixed boundary of consideration must be set. Thus, there is an ongoing negotiation to relate the two in systems practice and the judgment to do so is greatly helped by an appreciation of the difference between them.

Thus, a systems approach can be characterized by how it considers problems, solutions and the problem resolution process itself:

- Consider problems holistically, setting problem boundaries though understanding of natural system relationships and trying to avoid unwanted consequences.
- Create solutions based on sound system principles, in particular creating system structures which reduce organized complexity and unwanted emergent properties.
- Use understanding, judgment and models in both problem understanding and solution creation, while understanding the limitations of such views and models.

Systems Methodologies

One topic that has received significant attention in the systems science community is the analysis and comparison of methodologies which implement a systems approach. A methodology is a body of tools, procedures, and methods applied to a problem situation, ideally derived from a theoretical framework. These describe structured approaches to problem understanding and/or resolution, making use of some of the concepts of systems thinking. These methodologies are generally associated with a particular system paradigm or way of thinking, which has a strong influence on the three aspects of a systems approach described above.

The most widely used groups of methodologies are as follows (see also History of Systems Science):

- Hard system methodologies (Checkland 1978) set out to select an efficient means to achieve a predefined and agreed end.
- Soft system methodologies (Checkland 1999) are interactive and participatory approaches to assist groups of diverse participants to alleviate a complex, problematic situation of common interest.
- Critical systems thinking methodologies (Jackson 1985) attempt to provide a framework in which appropriate hard and soft methods can be applied as appropriate to the situation under investigation.

Systems Dynamics

Systems dynamics (SD) uses some of the ideas of cybernetics to consider the behavior of systems as a whole in their environment. SD was developed by Jay Forrester in the 1960's. He was interested in modeling the dynamic behavior of systems such as populations in cities, or industrial supply chains.

System dynamics (Forrester 1961) is an approach to understanding the behavior of complex systems over time. It deals with internal feedback loops and time delays that affect the behavior of the entire system. The main elements of SD are:

- The understanding of the dynamic interactions in a problem or solution as a system of feedback loops, modeled using a Causal Loop Diagram.

- Quantitative modeling of system performance as an accumulation of stocks (any entity or property which varies over time) and flows (representations of the rate of change of a stock).
- The creation of dynamic simulations, exploring how the value of key parameters change over time. A wide range of software tools are available to support this.

These elements help describe how even seemingly simple systems display baffling non-linearity.

Hard Systems Methodologies

Checkland (1975) classifies hard system (glossary) methodologies, which set out to select an efficient means to achieve a predefined end, under the following headings:

- Systems Analysis - the systematic appraisal of the costs and other implications of meeting a defined requirement in various ways.
- Systems Engineering (SE) - the set of activities that together lead to the creation of a complex man-made entity and/or the procedures and information flows associated with its operation.

Operational Research is also considered a hard system approach, closely related to the systems analysis approach developed by the Rand Corporation, in which solutions are known but the best combinations of these solutions must be found. There is some debate as to whether system dynamics is a hard approach, which is used to assess the objective behavior of real situations. Many applications of SD have focused on the system, however it can and has also been used as part of a soft approach including the modeling of subjective perceptions (Lane 2000).

SE allows for the creation of new solution systems, based upon available technologies. This hard view of SE as a solution focused approach applied to large, complex and technology focused solutions, is exemplified by (Jenkins 1969; Hall 1962) and early defense and aerospace standards.

It should be noted that historically the SE discipline was primarily aimed at developing, modifying or supporting hard systems. More recent developments in SE have incorporated problem focused thinking and agile solution approaches. It is this view of SE that is described in the SEBoK.

All of these hard approaches can use systems thinking to ensure complete and viable solutions are created and/or as part of the solution optimization process. These approaches are appropriate to unitary problems, but not when the problem situation or solution technologies are unclear.

Soft Systems and Problem Structuring Methods

Problem Structuring Methods (PSM) are interactive and participatory approaches to assist groups of diverse participants to alleviate a complex, problematic situation of common interest. Typically, the hardest element of the situation is framing the issues which constitute the problem (Minger and Resenhead 2004).

PSM use systems and systems thinking as an abstract framework for investigation, rather than a structure for creating solutions. Systems descriptions are used to understand the current situation and describe an idealized future. Interventions directly in the current organization to move towards the idea recognize that the assumptions and mental models of the participants are an important obstruction to change, and that these differing views cannot be dismissed but instead must form part of the intervention approach.

Peter Checkland's action research program (see Systems Science) in the 1980's forms the basis of work by Checkland, Wilson and others in the development of soft systems methodology (SSM) (Checkland 1999; Wilson 2001). SSM formalizes the idea of a soft approach using systemic thinking to expose the issues in a problem situation and guide interventions to reduce them. SSM provides a framework of ideas and models to help guide participants through this systemic thinking.

Other PSM approaches include interactive planning approach (Ackoff 1981), social systems design (Churchman 1968), and strategic assumptions surfacing and testing (Mason and Mitroff 1981).

SSM and other soft approaches use systems thinking to ensure problem situations are fully explored and resolved. These approaches are appropriate to pluralist problems. Critics of SSM suggest that it does not consider the process of intervention, and in particular how differences in power between individuals and social groups impact the effectiveness of interventions.

Critical Systems Thinking and Multi-Methodology

The development of a range of hard and soft methods naturally leads to the question of which method to apply in what set of circumstances (Jackson 1989). Critical systems thinking (CST) or **Critical Management Science** (Jackson 1985) attempts to deal with this question.

The word critical is used in two ways. Firstly, critical thinking considers the limits of knowledge and investigates the limits and assumptions of hard and soft systems, as discussed in the above sections. From this comes frameworks and meta-methodology that establish when to apply different methods such as **total systems intervention** (TSI) (Flood and Jackson 1991). Critical, "pluralist," or "pragmatic" **multi-methodology** approaches take this aspect of critical thinking one stage further to recognize the value of combining techniques from several hard, soft , or custom methods as needed (Mingers and Gill 1997). Many in the systems science community believe that the multi-methodology approach has been accepted as the de facto systems approach and that the challenges now are in refining tools and methods to support it.

Churchman (1979) and others have also considered broader ethics, political and social questions related to management science, with regards to the relative power and responsibility of the participants in system interventions. The second aspect of critical thinking considers the ethical, political, and coercive dimension in Jackson's System of Systems Methodologies (SOSM) framework (Jackson 2003) and the role of system thinking in society.

Selecting Systems Methodologies

Jackson proposes a frame for considering which approach should be applied (please see Jackson's Framework [1]). In Jackson's framework, the following definitions apply to the participants involved in solving the problem:

- Unitary: A problem situation in which participants "have similar values, beliefs and interests. They share common purposes and are all involved, in one way or another, in decision-making about how to realize their agreed objectives." (Jackson 2003, 19)
- Pluralist: A problem situation involving participants in which "although their basic interests are compatible, they do not share the same values and beliefs. Space needs to be made available within which debate, disagreement, even conflict, can take place. If this is done, and all feel they have been involved in decision-making, then accommodations and compromises can be found. Participants will come to agree, at least temporarily, on productive ways forward and will act accordingly." (Jackson 2003, 19)
- Coercive: A problem situation in which the participants "have few interests in common and, if free to express them, would hold conflicting values and beliefs. Compromise is not possible and so no agreed objectives direct action. Decisions are taken on the basis of who has most power and various forms of coercion employed to ensure adherence to commands." (Jackson 2003, 19)

Jackson's framework suggests that for simple and complex systems with unitary participants, hard and dynamic systems thinking applies, respectively. For simple and complex systems with pluralist participants, soft systems thinking applies. For simple and complex systems with coercive participants, **emancipatory** and postmodernist system thinking applies, respectively. These thinking approaches consider all attempts to look for system solutions to be temporary and ineffective in situations where the power of individuals and groups of people dominate any system structures we create. They advocate an approach which encourages diversity, free-thinking and creativity of individuals and in the organization's structures. Thus, modern systems thinking has the breadth needed to deal with a broad range of complex problems and solutions.

These ideas sit at the extreme of system thinking as a tool for challenging assumptions and stimulating innovative solutions in problem solving. Jackson (2003) identifies the work of some authors who have included these ideas into their systems approach.

Complexity

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Hillary Sillitto and Sarah Sheard

-

This article is part of the Systems Science knowledge area (KA). It gives the background of and an indication of current thinking on complexity and how it influences systems engineering (SE) practice.

Complexity is one of the most important and difficult to define system concepts. Is a system's complexity in the eye of the beholder, or is there inherent complexity in how systems are organized? Is there a single definitive definition of complexity and, if so, how can it be assessed and measured? This topic will discuss how these ideas relate to the general definitions of a system given in What is a System?, and in particular to the different engineered system contexts. This article is closely related to the emergence topic that follows it.

Defining System Complexity

Complexity has been considered by a number of authors from various perspectives; some of the discussions of complexity relevant to systems are described in the final section of this article. Sheard and Mostashari (Sheard and Mostashari 2011) synthesize many of these ideas to categorize complexity as follows:

1. **Structural Complexity** looks at the system elements and relationships. In particular, structural complexity looks at how many different ways system elements can be combined. Thus, it is related to the potential for the system to adapt to external needs.
2. **Dynamic Complexity** considers the complexity which can be observed when systems are used to perform particular tasks in an environment. There is a time element to dynamic complexity. The ways in which systems interact in the short term is directly related to system behavior; the longer-term effects of using systems in an environment is related to system evolution.

3. **Socio-Political Complexity** considers the effect of individuals or groups of people on complexity. People-related complexity has two aspects. One is related to the perception of a situation as complex or not complex, due to multiple stakeholder viewpoints within a system context and social or cultural biases which add to the wider influences on a system context. The other involves either the "irrational" behavior of an individual or the swarm behavior of many people behaving individually in ways that make sense; however, the emergent behavior is unpredicted and perhaps counterproductive. This latter type is based on the interactions of the people according to their various interrelationships and is often graphed using systems dynamics formalisms.

Thus, complexity is a measure of how difficult it is to understand how a system will behave or to predict the consequences of changing it. It occurs when there is no simple relationship between what an individual element does and what the system as a whole will do, and when the system includes some element of adaptation or problem solving to achieve its goals in different situations. It can be affected by objective attributes of a system such as by the number, types of and diversity of system elements and relationships, or by the subjective perceptions of system observers due to their experience, knowledge, training, or other sociopolitical considerations.

This view of complex systems provides insight into the kind of system for which systems thinking and a systems approach is essential.

Complexity and Engineered Systems

The different perspectives on complexity are not independent when considered across a systems context. The structural complexity of a system-of-interest (SoI) may be related to dynamic complexity when the SoI also functions as part of a wider system in different problem scenarios. People are involved in most system contexts, as part of the problem situation, as system elements and part of the operating environment. The human activity systems which we create to identify, design, build and support an engineered system and the wider social and business systems in which they sit are also likely to be complex and affect the complexity of the systems they produce and use.

Sheard and Mostashari (2011) show the ways different views of complexity map onto product system, service system and enterprise system contexts, as well as to associated development and sustainment systems and project organizations. Ordered systems occur as system components and are the subject of traditional engineering. It is important to understand the behaviors of such systems when using them in a complex system. One might also need to consider both truly random or chaotic natural or social systems as part of the context of an engineered system. The main focus for systems approaches is **organized complexity** (see below). This kind of complexity cannot be dealt with by traditional analysis techniques, nor can it be totally removed by the way we design or use solutions. A systems approach must be able to recognize and deal with such complexity across the life of the systems with which it interacts.

Sillitto (2014) considers the link between the types of system complexity and system architecture. The ability to understand, manage and respond to both objective and subjective complexity in the problem situation, the systems we develop or the systems we use to develop and sustain them is a key component of the Systems Approach Applied to Engineered Systems and hence to the practice of systems engineering.

Origins and Characteristics of Complexity

This section describes some of the prevailing ideas on complexity. Various authors have used different language to express these ideas. While a number of common threads can be seen, some of the ideas take different viewpoints and may be contradictory in nature.

One of the most widely used definitions of complexity is the degree of difficulty in predicting the properties of a system if the properties of the system's parts are given (generally attributed to Weaver). This, in turn, is related to the number of elements and connections between them. Weaver (Weaver 1948) relates complexity to types of elements and how they interact. He describes simplicity as problems with a finite number of variables and interaction, and identifies two kinds of complexity:

1. **Disorganized Complexity** is found in a system with many loosely coupled, disorganized and equal elements, which possesses certain average properties such as temperature or pressure. Such a system can be described by "19th Century" statistical analysis techniques.
2. **Organized Complexity** can be found in a system with many strongly coupled, organized and different elements which possess certain emergent properties and phenomena such as those exhibited by economic, political or social systems. Such a system cannot be described well by traditional analysis techniques.

Weaver's ideas about this new kind of complex problem are some of the foundational ideas of systems thinking. (See also Systems Thinking.)

Later authors, such as Flood and Carson (1993) and Lawson (2010), expand organized complexity to systems which have been organized into a structure intended to be understood and thus amenable to engineering and life cycle management (Braha et al. 2006). They also suggest that disorganized complexity could result from a heterogeneous complex system evolving without explicit architectural control during its life (complexity creep). This is a different use of the terms "organized" and "disorganized" to that used by Weaver. Care should be taken in mixing these ideas

Complexity should not be confused with "complicated". Many authors make a distinction between ordered and disordered collections of elements.

Ordered systems have fixed relationships between elements and are not adaptable. Page (2009) cites a watch as an example of something which can be considered an ordered system. Such a system is complicated, with many elements working together. Its components are based on similar technologies, with clear mapping between form and function. If the operating environment changes beyond prescribed limits, or one key component is removed, the watch will cease to perform its function.

In common usage, chaos is a state of disorder or unpredictability characterized by elements which are not interconnected and behave randomly with no adaptation or control. Chaos Theory (Kellert 1993) is applied to certain dynamic systems (e.g., the weather) which, although they have structure and relationships, exhibit unpredictable behavior. These systems may include aspects of randomness but can be described using deterministic models from which their behavior can be described given a set of initial conditions. However, their structure is such that (un-measurably) small perturbations in inputs or environmental conditions may result in unpredictable changes in behavior. Such systems are referred to as deterministically chaotic or, simply, chaotic systems. Simulations of chaotic systems can be created and, with increases in computing power, reasonable predictions of behavior are possible at least some of the time.

On a spectrum of order to complete disorder, complexity is somewhere in the middle, with more flexibility and change than complete order and more stability than complete disorder (Sheard and Mostashari 2009).

Complex systems may evolve "to the edge of chaos," resulting in systems which can appear deterministic but which exhibit counter intuitive behavior compared to that of more ordered systems. The statistics of chance events in a complex system are often characterized by a power-law distribution, the "signature of complexity" (Sheard 2005). The power-law distribution is found in a very wide variety of natural and man-made phenomena, and it means that the probability of a low probability—large impact event is much higher than a Gaussian distribution would suggest.

Such a system may react in a non-linear way to exhibit abrupt phase changes. These phase changes can be either reversible or irreversible. This has a major impact on engineered systems in terms of the occurrence, impact and public acceptance of risk and failure.

Objective complexity is an attribute of complex systems and is a measure of where a system sits on this spectrum. It is defined as the extent to which future states of the system cannot be predicted with certainty and precision, regardless of our knowledge of current state and history. Subjective complexity is a measure of how easy it is for an observer to understand a system or predict what it will do next. As such, it is a function of the perspective and comprehension of each individual. It is important to be prepared to mitigate subjective complexity with consistent, clear communication and strong stakeholder engagement (Sillitto 2009).

The literature has evolved to a fairly consistent definition of the characteristics of system elements and relationships for objective systems complexity. The following summary is given by Page (2009):

1. **Independence**: Autonomous system elements which are able to make their own decisions, influenced by information from other elements and the adaptability algorithms the autonomous elements carry with themselves (Sheard and Mostashari 2009).
2. **Interconnectedness**: System elements connect via a physical connection, shared data or simply a visual awareness of where the other elements are and what they are doing, as in the case of the flock of geese or the squadron of aircraft.
3. **Diversity**: System elements which are either technologically or functionally different in some way. For example, elements may be carrying different adaptability algorithms.
4. **Adaptability**: Self-organizing system elements which can do what they want to do to support themselves or the entire system in response to their environment (Sheard and Mostashari 2009). Adaptability is often achieved by human elements but can be achieved with software. Pollock and Hodgson (2004) describe how this can be done in a variety of complex system types, including power grids and enterprise systems.

Due to the variability of human behavior as part of a system and the perceptions of people outside the system, the inclusion of people in a system is often a factor in their complexity. People may be viewed as observing systems or as system elements which contribute to the other types of complexity (Axelrod and Cohen 1999). The rational or irrational behavior of individuals in particular situations is a vital factor in respect to complexity (Kline 1995). Some of this complexity can be reduced through education, training and familiarity with a system. Some is irreducible and must be managed as part of a problem or solution. Checkland (1999) argues that a group of stakeholders will have its own world views which lead them to form different, but equally valid, understandings of a system context. These differences cannot be explained away or analyzed out, and must be understood and considered in the formulation of problems and the creation of potential solutions.

Warfield (2006) developed a powerful methodology for addressing complex issues, particularly in the socio-economic field, based on a relevant group of people developing an understanding of the issue in the form of a set of interacting problems - what he called the “problematique”. The complexity is then characterized via several measures, such as the number of significant problems, their interactions and the degree of consensus about the nature of the problems. What becomes clear is that how, why, where and by whom a system is used may all contribute to its perceived complexity.

Sheard and Mostashari (2011) sort the attributes of complexity into causes and effects. Attributes that cause complexity include being non-linear; emergent; chaotic; adaptive; tightly coupled; self-organized; decentralized; open; political (as opposed to scientific); and multi-scale; as well as having many pieces. The effects of those attributes which make a system be perceived as complex include being uncertain; difficult to understand; unpredictable; uncontrollable; unstable; unrepairable; unmaintainable and costly; having unclear cause and effect; and taking too long to build.

Complexity and its relationship with difficultly

The Collins Dictionary (2024) defines difficulty as “a task, problem, etc., that is hard to deal with”, while the Oxford English dictionary (2024) defines difficult as “Needing much effort or skill to accomplish, deal with, or understand”.

There are many types of systems that fall into the difficult category: Complex, complicated and constrained systems are examples of difficult systems from the perspective of systems engineering. Complicated or intricate systems can be hard to understand, and hence difficult. Complex systems are hard to predict because they are not understood, or otherwise leading to a breakdown in causality, and hence are difficult. Achieving an outcome when heavily constrained by cost, resource or time can also be very difficult.

A richer understanding of Complex systems and proposed definitions for complex, complicated and simple systems are available in the “A Complexity Primer for Systems Engineers, Revision 1, 2021.

-

This topic forms part of the Systems Science knowledge area (KA). It gives the background to some of the ways in which emergence has been described, as well as an indication of current thinking on what it is and how it influences systems engineering (SE) practice. It will discuss how these ideas relate to the general definitions of systems given in What is a System?; in particular, how they relate to different engineered system contexts. This topic is closely related to the complexity topic that precedes it.

Emergence is a consequence of the fundamental system concepts of holism and interaction (Hitchins 2007, 27). System wholes have behaviors and properties arising from the organization of their elements and their relationships, which only become apparent when the system is placed in different environments.

Questions that arise from this definition include: What kinds of systems exhibit different kinds of emergence and under what conditions? Can emergence be predicted, and is it beneficial or detrimental to a system? How do we deal with emergence in the development and use of engineered systems? Can it be planned for? How?

There are many varied and occasionally conflicting views on emergence. This topic presents the prevailing views and provides references for others.

Overview of Emergence

As defined by Checkland, emergence is “the principle that entities exhibit properties which are meaningful only when attributed to the whole, not to its parts.” (Checkland 1999, 314). Emergent system behavior can be viewed as a consequence of the interactions and relationships between system elements rather than the behavior of individual elements. It emerges from a combination of the behavior and properties of the system elements and the systems structure or allowable interactions between the elements, and may be triggered or influenced by a stimulus from the systems environment.

Emergence is common in nature. The pungent gas ammonia results from the chemical combination of two odorless gases, hydrogen and nitrogen. As individual parts, feathers, beaks, wings, and gullets do not have the ability to overcome gravity; however, when properly connected in a bird, they create the emergent behavior of flight. What we refer to as “self-awareness” results from the combined effect of the interconnected and interacting neurons that make up the brain (Hitchins 2007, 7).

Hitchins also notes that technological systems exhibit emergence. We can observe a number of levels of outcome which arise from interaction between elements in an engineered system context. At a simple level, some system outcomes or attributes have a fairly simple and well defined mapping to their elements; for example, center of gravity or top speed of a vehicle result from a combination of element properties and how they are combined. Other behaviors can be associated with these simple outcomes, but their value emerges in complex and less predictable ways across a system. The single lap performance of a vehicle around a track is related to center of gravity and speed; however, it is also affected by driver skill, external conditions, component ware, etc. Getting the 'best' performance from a vehicle can only be achieved by a combination of good design and feedback from real laps under race conditions.

There are also outcomes which are less tangible and which come as a surprise to both system developers and users. How does lap time translate into a winning motor racing team? Why is a sports car more desirable to many than

other vehicles with performances that are as good or better?

Emergence can always be observed at the highest level of system. However, Hitchins (2007, 7) also points out that to the extent that the systems elements themselves can be considered as systems, they also exhibit emergence. Page (2009) refers to emergence as a "macro-level property." Ryan (2007) contends that emergence is coupled to scope rather than system hierarchical levels. In Ryan's terms, scope has to do with spatial dimensions (how system elements are related to each other) rather than hierarchical levels.

Abbott (2006) does not disagree with the general definition of emergence as discussed above. However, he takes issue with the notion that emergence operates outside the bounds of classical physics. He says that "such higher-level entities…can always be reduced to primitive physical forces."

Bedau and Humphreys (2008) and Francois (2004) provide comprehensive descriptions of the philosophical and scientific background of emergence.

Types of Emergence

A variety of definitions of types of emergence exists. See Emmeche et al. (1997), Chroust (2003) and O'Connor and Wong (2006) for specific details of some of the variants. Page (2009) describes three types of emergence: "simple", "weak", and "strong".

According to Page, **simple emergence** is generated by the combination of element properties and relationships and occurs in non-complex or "ordered" systems (see Complexity) (2009). To achieve the emergent property of "controlled flight" we cannot consider only the wings, or the control system, or the propulsion system. All three must be considered, as well as the way these three are interconnected-with each other, as well as with all the other parts of the aircraft. Page suggests that simple emergence is the only type of emergence that can be predicted. This view of emergence is also referred to as synergy (Hitchins 2009).

Page describes **weak emergence** as expected emergence which is desired (or at least allowed for) in the system structure (2009). However, since weak emergence is a product of a complex system, the actual level of emergence cannot be predicted just from knowledge of the characteristics of the individual system components.

The term **strong emergence** is used to describe unexpected emergence; that is, emergence not observed until the system is simulated or tested or, more alarmingly, until the system encounters in operation a situation that was not anticipated during design and development.

Strong emergence may be evident in failures or shutdowns. For example, the US-Canada Blackout of 2003 as described by the US-Canada Power System Outage Task Force (US-Canada Power Task Force 2004) was a case of cascading shutdown that resulted from the design of the system. Even though there was no equipment failure, the shutdown was systemic. As Hitchins points out, this example shows that emergent properties are not always beneficial (Hitchins 2007, 15).

Other authors make a different distinction between the ideas of strong, or unexpected, emergence and unpredictable emergence:

- Firstly, there are the unexpected properties that could have been predicted but were not considered in a systems development: "Properties which are unexpected by the observer because of his incomplete data set, with regard to the phenomenon at hand" (Francois, C. 2004, 737). According to Jackson et al. (2010), a desired level of emergence is usually achieved by iteration. This may occur as a result of evolutionary processes, in which element properties and combinations are "selected for", depending on how well they contribute to a system's effectiveness against environmental pressures or by iteration of design parameters through simulation or build/test cycles. Taking this view, the specific values of weak emergence can be refined, and examples of strong emergence can be considered in subsequent iterations so long as they are amenable to analysis.
- Secondly, there are unexpected properties which cannot be predicted from the properties of the system's components: "Properties which are, in and of themselves, not derivable a priori from the behavior of the parts of

the system" (Francois, C. 2004, 737). This view of emergence is a familiar one in social or natural sciences, but more controversial in engineering. We should distinguish between a theoretical and a practical unpredictability (Chroust 2002). The weather forecast is theoretically predictable, but beyond certain limited accuracy practically impossible due to its chaotic nature. The emergence of consciousness in human beings cannot be deduced from the physiological properties of the brain. For many, this genuinely unpredictable type of complexity has limited value for engineering. (See **Practical Considerations** below.)

A type of system particularly subject to strong emergence is the system of systems (sos). The reason for this is that the SoS, by definition, is composed of different systems that were designed to operate independently. When these systems are operated together, the interaction among the parts of the system is likely to result in unexpected emergence. Chaotic or truly unpredictable emergence is likely for this class of systems.

Emergent Properties

Emergent properties can be defined as follows: “A property of a complex system is said to be ‘emergent’ [in the case when], although it arises out of the properties and relations characterizing its simpler constituents, it is neither predictable from, nor reducible to, these lower-level characteristics” (Honderich 1995, 224).

All systems can have emergent properties which may or may not be predictable or amenable to modeling, as discussed above. Much of the literature on complexity includes emergence as a defining characteristic of complex systems. For example, Boccara (2004) states that “The appearance of emergent properties is the single most distinguishing feature of complex systems.” In general, the more ordered a system is, the easier its emergent properties are to predict. The more complex a system is, the more difficult predicting its emergent properties becomes.

Some practitioners use the term “emergence” only when referring to “strong emergence”. These practitioners refer to the other two forms of emergent behavior as synergy or “system level behavior” (Chroust 2002). Taking this view, we would reserve the term "Emergent Property" for unexpected properties, which can be modeled or refined through iterations of the systems development.

Unforeseen emergence causes nasty shocks. Many believe that the main job of the systems approach is to prevent undesired emergence in order to minimize the risk of unexpected and potentially undesirable outcomes. This review of emergent properties is often specifically associated with identifying and avoiding system failures (Hitchins 2007).

Good SE isn't just focused on avoiding system failure, however. It also involves maximizing opportunity by understanding and exploiting emergence in engineered systems to create the required system level characteristics from synergistic interactions between the components, not just from the components themselves (Sillitto 2010).

One important group of emergent properties includes properties such as agility and resilience. These are critical system properties that are not meaningful except at the whole system level.

Practical Considerations

As mentioned above, one way to manage emergent properties is through iteration. The requirements to iterate the design of an engineered system to achieve desired emergence results in a design process are lengthier than those needed to design an ordered system. Creating an engineered system capable of such iteration may also require a more configurable or modular solution. The result is that complex systems may be more costly and time-consuming to develop than ordered ones, and the cost and time to develop is inherently less predictable.

Sillitto (2010) observes that “engineering design domains that exploit emergence have good mathematical models of the domain, and rigorously control variability of components and subsystems, and of process, in both design and operation.” The iterations discussed above can be accelerated by using simulation and modeling, so that not all the iterations need to involve building real systems and operating them in the real environment.

The idea of domain models is explored further by Hybertson in the context of general models or patterns learned over time and captured in a model space (Hybertson 2009). Hybertson states that knowing what emergence will appear from a given design, including side effects, requires hindsight. For a new type of problem that has not been solved, or a new type of system that has not been built, it is virtually impossible to predict emergent behavior of the solution or system. Some hindsight, or at least some insight, can be obtained by modeling and iterating a specific system design; however, iterating the design within the development of one system yields only limited hindsight and often does not give a full sense of emergence and side effects.

True hindsight and understanding comes from building multiple systems of the same type and deploying them, then observing their emergent behavior in operation and the side effects of placing them in their environments. If those observations are done systematically, and the emergence and side effects are distilled and captured in relation to the design of the systems — including the variations in those designs — and made available to the community, then we are in a position to predict and exploit the emergence.

Two factors are discovered in this type of testing environment: what works (that is, what emergent behavior and side effects are desirable); and what does not work (that is, what emergent behavior and side effects are undesirable). What works affirms the design. What does not work calls for corrections in the design. This is why multiple systems, especially complex systems, must be built and deployed over time and in different environments - to learn and understand the relations among the design, emergent behavior, side effects, and environment.

These two types of captured learning correspond respectively to patterns and “antipatterns,” or patterns of failure, both of which are discussed in a broader context in the Principles of Systems Thinking and Patterns of Systems Thinking topics.

The use of iterations to refine the values of emergent properties, either across the life of a single system or through the development of patterns encapsulating knowledge gained from multiple developments, applies most easily to the discussion of strong emergence above. In this sense, those properties which can be observed but cannot be related to design choices are not relevant to a systems approach. However, they can have value when dealing with a combination of engineering and managed problems which occur for system of systems contexts (Sillitto 2010). (See Systems Approach Applied to Engineered Systems.)

-

This knowledge area (KA) provides a guide to knowledge about systems thinking which is the integrating paradigm for systems science and systems approaches to practice.

This is part of the wider systems knowledge which can help to provide a common language and intellectual foundation, and make practical systems concepts, principles, patterns and tools accessible to systems engineering (SE), as discussed in the Introduction to Part 2.

Topics

Each part of the Guide to the SE Body of Knowledge (SEBoK) is divided into KAs, which are groupings of information with a related theme. The KAs, in turn, are divided into topics. This KA contains the following topics:

- What is Systems Thinking?
- Concepts of Systems Thinking
- Principles of Systems Thinking
- Patterns of Systems Thinking

Introduction

Systems thinking is concerned with understanding or intervening in problem situations, based on the principles and concepts of the systems paradigm. This KA offers some basic definitions of systems thinking. The following diagram summarizes how the knowledge is presented.

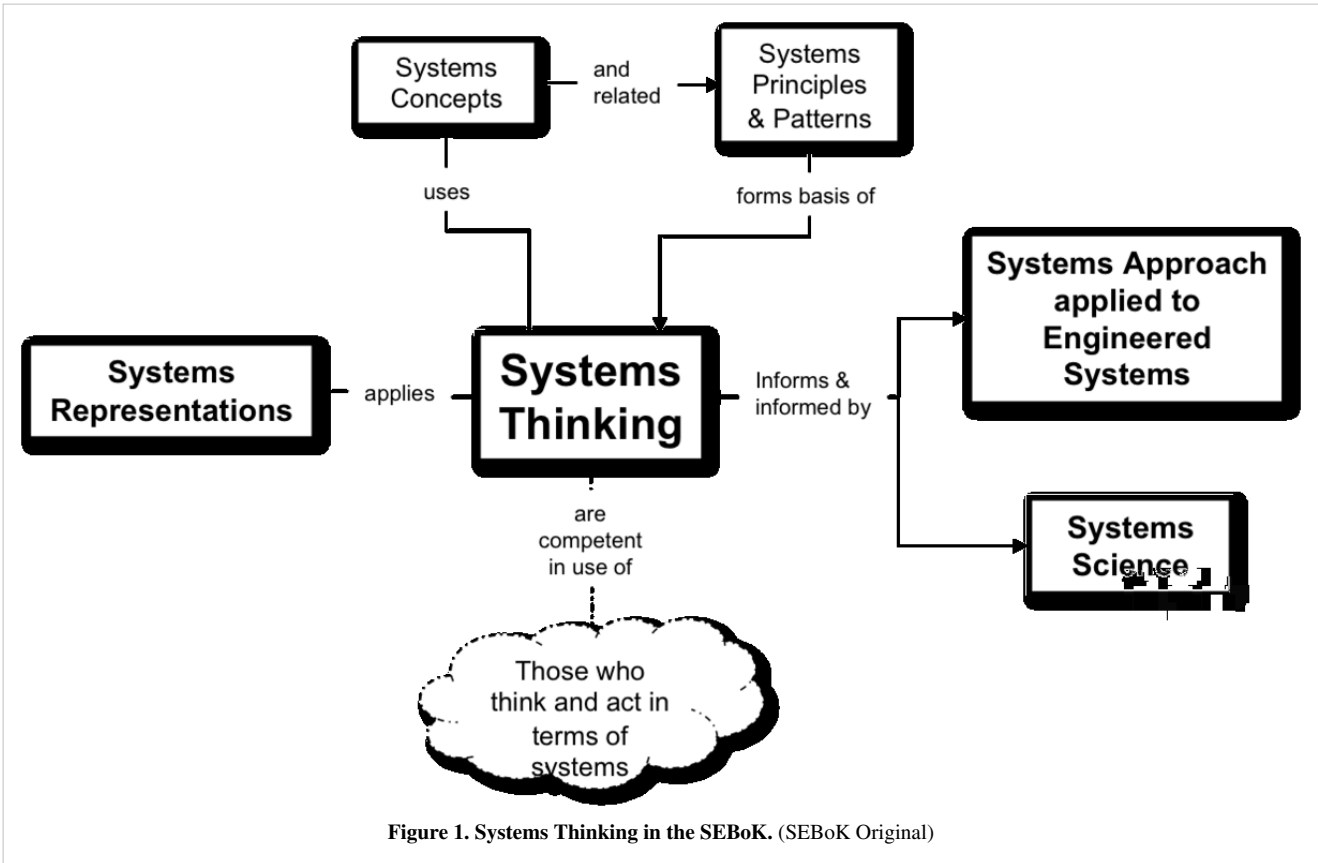

Figure 1. Systems Thinking in the SEBoK. (SEBoK Original)

Systems thinking considers the similarities between systems from different domains in terms of a set of common systems concepts, principles and patterns:

- A principle is a rule of conduct or behavior. To take this further, a principle is a “basic generalization that is accepted as true and that can be used as a basis for reasoning or conduct” (WordWeb.com).
- A concept is an abstraction, or a general idea inferred or derived from specific instances.

Principles depend on concepts in order to state a “truth.” Hence, principles and concepts go hand in hand; principles cannot exist without concepts and concepts are not very useful without principles to help guide the proper way to act (Lawson and Martin 2008).

Many sources combine both concepts and the principles based on them. The Concepts of Systems Thinking article presents concepts extracted from a variety of theory and practice sources. The Principles of Systems Thinking article, in turn, presents a summary of important principles referring back to the concepts upon which they are based.

A pattern is an expression of observable similarities found in systems from different domains. Patterns exist in both natural and man-made systems and are used in systems science and systems engineering. A summary of the different classes of patterns and the use of patterns to support a systems approach is discussed in the final Patterns of Systems Thinking article.

The practical application of systems thinking often employs the use of abstract system representations or models. Some mention of models is made in this KA; additionally, a more complete guide is provided in Representing Systems with Models.

What is Systems Thinking?

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Brian Wells and Bud Lawson

-

This topic is part of the Systems Thinking knowledge area (KA). The scope of systems thinking is a starting point for dealing with real world situations using a set of related systems concepts discussed in the Concepts of Systems Thinking topic, systems principles discussed in the Principles of Systems Thinking topic, and system patterns discussed in the Patterns of Systems Thinking topic.

Introduction

The concepts, principles, and patterns of systems thinking have arisen both from the work of systems scientists and from the work of practitioners applying the insights of systems science to real-world problems.

Holism has been a dominant theme in systems thinking for nearly a century, in recognition of the need to consider a system as a whole because of observed phenomena such as emergence. Proponents have included Wertheimer, Smuts, Bertalanffy, Weiss, (Ackoff 1979), (Klir 2001), and (Koestler 1967) among many others.

A more detailed discussion of the most important movements in systems theory can be found in History of Systems Science.

Identifying Systems of Interest

When humans observe or interact with a system, they allocate boundaries and names to parts of the system. This naming may follow the natural hierarchy of the system, but will also reflect the needs and experience of the observer to associate elements with common attributes of purposes relevant to their own. Thus, a number of systems of interest (SoIs) (Flood and Carson 1993) must be identified and they must be both relevant and include a set of elements which represent a system whole. This way of observing systems wherein the complex system relationships are focused around a particular system boundary is called **systemic resolution**.

Systems thinking requires an ongoing process of attention and adaptation to ensure that one has appropriately identified boundaries, dependencies, and relationships. Churchman (1968) and others have also considered broader ethical, political, and social questions related to management science with regards to the relative power and responsibility of the participants in system interventions. These are seen by critical systems thinkers as key factors to be considered in defining problem system boundaries.

A system context can be used to define a SoI and to capture and agree on the important relationships between it, such as the systems which it works with directly and the systems which influence it in some way. When this approach is used to focus on part of a larger system, a balance of reductionism and holism is applied. This balance sits at the heart of a systems approach. A systems context provides the tool for applying this balance and is thus an essential part of any systems approach and hence, of systems engineering (SE) as well. Approaches for describing the context of the different types of engineered systems are discussed in the Engineered System Context topic within the Systems Approach Applied to Engineered Systems KA.

Thoughts on Systems Thinking

Senge (1990) discusses systems thinking in a number of ways as

> *a discipline for seeing wholes ... a framework for seeing interrelationships rather than things ... a process of discovery and diagnosis ... and as a sensibility for the subtle interconnectedness that gives living systems their unique character.*(Senge 2006, 68-69)

Churchman came to define a systems approach as requiring consideration of a system from the viewpoint of those outside its boundary (Churchman 1979). There are many demonstrations that choosing too narrow a boundary, either in terms of scope or timeline, results in the problem of the moment being solved only at the expense of a similar or bigger problem being created somewhere else in space, community, or time (Senge 2006) and (Meadows 1977). This is the “shifting the burden” archetype described in Patterns of Systems Thinking topic.

Churchman believes that an important component of system knowledge comes from "others" or "enemies" outside the system; the systems approach begins when first you see the world through the eyes of another (Churchman 1968). In this famous phrase, Churchman suggests that people can step outside a system they are in and mentally try to consider it through the lenses of other people's values. Churchman (1979) identified four main enemies of the systems approach namely: politics, morality, religion and aesthetics.

To Churchman, the "enemies" of the systems approach provide a powerful way of learning about the systems approach, precisely because they enable the rational thinker to step outside the boundary of a system and to look at it. It means that systems thinkers are not necessarily just involved within a system but are essentially involved in reasoning and decisions "outside" of systems rationality.

Some additional perspectives on systems thinking definitions are as follows:

- “Systems thinking requires the consciousness of the fact that we deal with models of our reality and not with the reality itself.” (Ossimitz 1997, 1)
- “…what is often called ‘systemic thinking’ …is …a bundle of capabilities, and at the heart of it is the ability to apply our normal thought processes, our common sense, to the circumstances of a given situation.” (Dörner 1996, 199)
- “Systems thinking provides a powerful way of taking account of causal connections that are distant in time and space.” (Stacey 2000, 9)

Chaos and complexity theories have also impacted the development of systems thinking, including the treatment of such concepts as emergence. According to Gharajedaghi:

> *Systems thinking is the art of simplifying complexity. It is about seeing through chaos, managing interdependency, and understanding choice. We see the world as increasingly more complex and chaotic because we use inadequate concepts to explain it. When we understand something, we no longer see it as chaotic or complex.* (Gharajedaghi 1999, 283)

Kasser considers systems thinking to be one element in a wider system of holistic thinking. Kasser defines holistic thinking as follows: "...the combination of analysis [in the form of elaboration], systems thinking and critical thinking" (Kasser 2010).

Systems Thinking and the Guide to the Systems Engineering Body of Knowledge

From these discussions, one can see systems thinking as both a set of founding ideas for the development of systems theories and practices and also as a pervasive way of thinking needed by those developing and applying those theories.

The SEBoK is particularly focused on how systems thinking can support a systems approach to engineered systems.

In order to examine a SoI in more detail, to understand, use, or change it in some way, practitioners are faced with an apparent "systems thinking paradox." One can only truly understand a system by considering all of its possible relationships and interactions, inside and outside of its boundary and in all possible future situations (of both system creation and life), but this makes it apparently impossible for people to understand a system or to predict all of the consequences of changes to it.

If this means that all possible system relationships and environmental conditions must be considered to fully understand the consequences of creating or changing a system, what useful work can be done?

In many ways this is the essence of all human endeavors, whether they are technical, managerial, social or political, the so-called *known knowns* and *unknown unknowns*. The systems approach is a way of tackling real world problems and making use of the concepts, principles and patterns of systems thinking to enable systems to be engineered and used.

The systems principles of encapsulation and separation of concerns in Principles of Systems Thinking relate to this issue. Some of the detail of complex situations must be hidden to allow focus on changes to a system element. The impact must be considered of any changes that might be made across sufficient related system components to fit within the acceptable commercial and social risks that must be considered. Engineering and management disciplines deal with this by gathering as much knowledge as necessary to proceed at a risk level acceptable to the required need. The assessment of what is enough and how much risk to take can, to some extent, be codified with rules and regulations, and managed through processes and procedures; however, it is ultimately a combination of the skill and judgment of the individuals performing the work.

Concepts of Systems Thinking

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Scott Jackson, Janet Singer, and Duane Hybertson

-

This article forms part of the Systems Thinking knowledge area (KA). It describes systems concepts, knowledge that can be used to understand problems and solutions to support systems thinking.

The concepts below have been synthesized from a number of sources, which are themselves summaries of concepts from other authors. Ackoff (1971) proposed a system of system concepts as part of general system theory (GST); Skyttner (2001) describes the main GST concepts from a number of systems science authors; Flood and Carlson (1993) give a description of concepts as an overview of systems thinking; Hitchins (2007) relates the concepts to systems engineering practice; and Lawson (2010) describes a system of system concepts where systems are categorized according to fundamental concepts, types, topologies, focus, complexity, and roles.

Wholeness and Interaction

A system is defined by a set of elements which exhibit sufficient cohesion, or "togetherness," to form a bounded whole (Hitchins 2007; Boardman and Sauser 2008).

According to Hitchins, interaction between elements is the "key" system concept (Hitchins 2009, 60). The focus on interactions and holism is a push-back against the perceived reductionist focus on parts and provides recognition that in complex systems, the interactions among parts is at least as important as the parts themselves.

An open system is defined by the interactions between system elements within a system boundary and by the interaction between system elements and other systems within an environment (see What is a System?). The remaining concepts below apply to open systems.

Regularity

Regularity is a uniformity or similarity that exists in multiple entities or at multiple times (Bertalanffy 1968). Regularities make science possible and engineering efficient and effective. Without regularities, we would be forced to consider every natural and artificial system problem and solution as unique. We would have no scientific laws, no categories or taxonomies, and each engineering effort would start from a clean slate.

Similarities and differences exist in any set or population. Every system problem or solution can be regarded as unique, but no problem/solution is in fact entirely unique. The nomothetic approach assumes regularities among entities and investigates what the regularities are. The idiographic approach assumes each entity is unique and investigates the unique qualities of entities, (Bertalanffy 1975).

A very large amount of regularity exists in both natural systems and engineered systems. Patterns of systems thinking capture and exploit that regularity.

State and Behavior

Any quality or property of a system element is called an attribute. The state of a system is a set of system attributes at a given time. A **system event** describes any change to theenvironment of a system, and hence its state:

- **Static** - A single state exists with no events.
- **Dynamic** - Multiple possible stable states exist.
- **Homeostatic** - System is static but its elements are dynamic. The system maintains its state by internal adjustments.

A stable state is one in which a system will remain until another event occurs.

State can be monitored using state variables, values of attributes which indicate the system state. The set of possible values of state variables over time is called the "'state space'". State variables are generally continuous but can be modeled using a finite state model (or "state machine").

Ackoff (1971) considers "change" to be how a system is affected by events, and system behavior as the effect a system has upon its environment. A system can

- **react** to a request by turning on a light,
- **respond** to darkness by deciding to turn on the light, or
- **act** to turn on the lights at a fixed time, randomly or with discernible reasoning.

A stable system is one which has one or more stable states within an environment for a range of possible events:

- **Deterministic** systems have a one-to-one mapping of state variables to state space, allowing future states to be predicted from past states.
- **Non-Deterministic** systems have a many-to-many mapping of state variables; future states cannot be reliably predicted.

The relationship between determinism and system complexity, including the idea of chaotic systems, is further discussed in the Complexity article.

Survival Behavior

Systems often behave in a manner that allows them to sustain themselves in one or more alternative viable states. Many natural or social systems have this goal, either consciously or as a "self organizing" system, arising from the interaction between elements.

Entropy is the tendency of systems to move towards disorder or disorganization. In physics, entropy is used to describe how organized heat energy is “lost” into the random background energy of the surrounding environment (the 2nd Law of Thermodynamics). A similar effect can be seen in engineered systems. What happens to a building or garden left unused for any time? Entropy can be used as a metaphor for aging, skill fade, obsolescence, misuse, boredom, etc.

"Negentropy" describes the forces working in a system to hold off entropy. Homeostasis is the biological equivalent of this, describing behavior which maintains a "steady state" or "dynamic equilibrium." Examples in nature include human cells, which maintain the same function while replacing their physical content at regular intervals. Again, this can be used as a metaphor for the fight against entropy, e.g. training, discipline, maintenance, etc.

Hitchins (2007) describes the relationship between the viability of a system and the number of connections between its elements. Hitchins's concept of connected variety states that stability of a system increases with its connectivity (both internally and with its environment). (See variety.)

Goal Seeking Behavior

Some systems have reasons for existence beyond simple survival. Goal seeking is one of the defining characteristics of engineered systems:

- A **goal** is a specific outcome which a system can achieve in a specified time
- An **objective** is a longer-term outcome which can be achieved through a series of goals.
- An **ideal** is an objective which cannot be achieved with any certainty, but for which progress towards the objective has value.

Systems may be single-goal seeking (perform set tasks), multi-goal seeking (perform related tasks), or reflective (set goals to tackle objectives or ideas). There are two types of goal seeking systems:

- Purposive systems have multiple goals with some shared outcome. Such a system can be used to provide pre-determined outcomes within an agreed time period. This system may have some freedom to choose how to achieve the goal. If it has memory, it may develop processes describing the behaviors needed for defined goals. Most machines or software systems are purposive.
- Purposeful systems are free to determine the goals needed to achieve an outcome. Such a system can be tasked to pursue objectives or ideals over a longer time through a series of goals. Humans and sufficiently complex machines are purposeful.

Control Behavior

Cybernetics, the science of control, defines two basic control mechanisms:

- **Negative feedback**, maintaining system state against set objectives or levels.
- **Positive feedback**, forced growth or contraction to new levels.

One of the main concerns of cybernetics is the balance between stability and speed of response. A black-box system view looks at the whole system. Control can only be achieved by carefully balancing inputs with outputs, which reduces speed of response. A white-box system view considers the system elements and their relationships; control mechanisms can be embedded into this structure to provide more responsive control and associated risks to stability.

Another useful control concept is that of a "meta-system", which sits over the system and is responsible for controlling its functions, either as a black-box or white-box. In this case, behavior arises from the combination of system and meta-system.

Control behavior is a trade between:

- **Specialization**, the focus of system behavior to exploit particular features of its environment, and
- Flexibility, the ability of a system to adapt quickly to environmental change.

While some system elements may be optimized for specialization, a temperature sensitive switch, flexibility, or an autonomous human controller, complex systems must strike a balance between the two for best results. This is an example of the concept of dualism, discussed in more detail in Principles of Systems Thinking.

Variety describes the number of different ways elements can be controlled and is dependent on the different ways in which they can then be combined. The Law of Requisite Variety states that a control system must have at least as much variety as the system it is controlling (Ashby 1956).

Function

Ackoff defines functions as outcomes which contribute to goals or objectives. To have a function, a system must be able to provide the outcome in two or more different ways. (This is called **equifinality**.)

This view of function and behavior is common in systems science. In this paradigm, all system elements have behavior of some kind; however, to be capable of functioning in certain ways requires a certain richness of behaviors.

In most hard systems approaches, a set of functions are described from the problem statement and then associated with one or more alternative element structures (Flood and Carson 1993). This process may be repeated until a system component (implementable combination of function and structure) has been defined (Martin 1997). Here, function is defined as either a task or activity that must be performed to achieve a desired outcome or as a transformation of inputs to outputs. This transformation may be:

- **Synchronous**, a regular interaction with a closely related system, or
- **Asynchronous**, an irregular response to a demand from another system that often triggers a set response.

The behavior of the resulting system is then assessed as a combination of function and effectiveness. In this case, behavior is seen as an external property of the system as a whole and is often described as analogous to human or organic behavior (Hitchins 2009).

Hierarchy, Emergence and Complexity

System behavior is related to combinations of element behaviors. Most systems exhibit **increasing variety**; i.e., they have behavior resulting from the combination of element behaviors. The term "synergy," or weak emergence, is used to describe the idea that the whole is greater than the sum of the parts. This is generally true; however, it is also possible to get **reducing variety**, in which the whole function is less than the sum of the parts (Hitchins 2007).

Complexity frequently takes the form of hierarchies. Hierarchic systems have some common properties independent of their specific content, and they will evolve far more quickly than non-hierarchic systems of comparable size (Simon 1996). A natural system hierarchy is a consequence of wholeness, with strongly cohesive elements grouping together forming structures which reduce complexity and increase robustness (Simon 1962).

Encapsulation is the enclosing of one thing within another. It may also be described as the degree to which it is enclosed. System encapsulation encloses system elements and their interactions from the external environment, and usually involves a system boundary that hides the internal from the external; for example, the internal organs of the human body can be optimized to work effectively within tightly defined conditions because they are protected from extremes of environmental change.

Socio-technical systems form what are known as control hierarchies, with systems at a higher level having some ownership of control over those at lower levels. Hitchins (2009) describes how systems form "preferred patterns" which can be used to enhance the stability of interacting systems hierarchies.

Looking across a hierarchy of systems generally reveals increasing complexity at the higher level, relating to both the structure of the system and how it is used. The term emergence describes behaviors emerging across a complex system hierarchy.

Effectiveness, Adaptation and Learning

Systems effectiveness is a measure of the system's ability to perform the functions necessary to achieve goals or objectives. Ackoff (1971) defines this as the product of the number of combinations of behavior to reach a function and the efficiency of each combination.

Hitchins (2007) describes effectiveness as a combination of **performance** (how well a function is done in ideal conditions), **availability** (how often the function is there when needed), and **survivability** (how likely is it that the system will be able to use the function fully).

System elements and their environments change in a positive, neutral or negative way in individual situations. An adaptive system is one that is able to change itself or its environment if its effectiveness is insufficient to achieve its current or future objectives. Ackoff (1971) defines four types of adaptation, changing the environment or the system in response to internal or external factors.

A system may also **learn**, improving its effectiveness over time without any change in state or goal.

Principles of Systems Thinking

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Scott Jackson, Janet Singer, and Duane Hybertson

-

This topic forms part of the Systems Thinking knowledge area (KA). It identifies systems principles as part of the basic ideas of systems thinking.

Some additional concepts more directly associated with engineered systems are described, and a summary of systems principles associated with the concepts already defined is provided. A number of additional “laws” and heuristics are also discussed.

Systems Principles, Laws, and Heuristics

A principle is a general rule of conduct or behavior (Lawson and Martin 2008). It can also be defined as a basic generalization that is accepted as true and that can be used as a basis for reasoning or conduct (WordWeb 2012c). Thus, systems principles can be used as a basis for reasoning about systems thinking or associated conduct (systems approaches).

Separation of Concerns

A systems approach is focused on a systems-of-interest (SoI) of an open system. This SoI consists of open, interacting subsystems that as a whole interact with and adapt to other systems in an environment. The systems approach also considers the SoI in its environment to be part of a larger, wider, or containing system (Hitchins 2009).

In the What is Systems Thinking? topic, a “systems thinking paradox” is discussed. How is it possible to take a holistic system view while still being able to focus on changing or creating systems?

Separation of concerns describes a balance between considering parts of a system problem or solution while not losing sight of the whole (Greer 2008). Abstraction is the process of taking away characteristics from something in order to reduce it to a set of base characteristics (SearchCIO 2012). In attempting to understand complex situations, it is easier to focus on bounded problems, whose solutions still remain agnostic to the greater problem (Erl 2012). This process sounds reductionist, but it can be applied effectively to systems. The key to the success of this approach is ensuring that one of the selected problems is the concern of the system as a whole. Finding balance between using

abstraction to focus on specific concerns while ensuring the whole is continually considered is at the center of systems approaches. A view is a subset of information observed of one or more entities, such as systems. The physical or conceptual point from which a view is observed is the viewpoint, which can be motivated by one or more observer concerns. Different views of the same target must be both separate, to reflect separation of concerns, and integrated such that all views of a given target are consistent and form a coherent whole (Hybertson 2009). Some sample views of a system are internal (Of what does it consist?), external (What are its properties and behavior as a whole?), static (What are its parts or structures?); and dynamic (interactions).

encapsulation, which encloses system elements and their interactions from the external environment, is discussed in Concepts of Systems Thinking. Encapsulation is associated with modularity, the degree to which a system's components may be separated and recombined (Griswold 1995). Modularity applies to systems in natural, social, and engineered domains. In engineering, encapsulation is the isolation of a system function within a module; it provides precise specifications for the module (IEEE Std. 610.12-1990).

Dualism is a characteristic of systems in which they exhibit seemingly contradictory characteristics that are important for the system (Hybertson 2009). The yin yang concept in Chinese philosophy emphasizes the interaction between dual elements and their harmonization, ensuring a constant dynamic balance through a cyclic dominance of one element and then the other, such as day and night (IEP 2006).

From a systems perspective, the interaction, harmonization, and balance between system properties is important. Hybertson (2009) defines **leverage** as the duality between:

- **Power**, the extent to which a system solves a specific problem, and
- **Generality**, the extent to which a system solves a whole class of problems.

While some systems or elements may be optimized for one extreme of such dualities, a dynamic balance is needed to be effective in solving complex problems.

Summary of Systems Principles

A set of systems principles is given in Table 1 below. The "Names" segment points to concepts underlying the principle. (See Concepts of Systems Thinking). Following the table, two additional sets of items related to systems principles are noted and briefly discussed: prerequisite laws for design science, and heuristics and pragmatic principles.

Table 1. A Set of Systems Principles. (SEBoK Original)

Name	Statement of Principle
Abstraction	A focus on essential characteristics is important in problem solving because it allows problem solvers to ignore the nonessential, thus simplifying the problem (Sci-Tech Encyclopedia 2009; SearchCIO 2012; Pearce 2012).
Boundary	A boundary or membrane separates the system from the external world. It serves to concentrate interactions inside the system while allowing exchange with external systems (Hoagland, Dodson, and Mauck 2001).
Change	Change is necessary for growth and adaptation, and should be accepted and planned for as part of the natural order of things rather than something to be ignored, avoided, or prohibited (Bertalanffy 1968; Hybertson 2009).
Dualism	Recognize dualities and consider how they are, or can be, harmonized in the context of a larger whole (Hybertson 2009).
Encapsulation	Hide internal parts and their interactions from the external environment (Klerer 1993; IEEE 1990).
Equifinality	In open systems, the same final state may be reached from different initial conditions and in different ways (Bertalanffy 1968). This principle can be exploited, especially in systems of purposeful agents.
Holism	A system should be considered as a single entity, a whole, not just as a set of parts (Ackoff 1979; Klir 2001).
Interaction	The properties, capabilities, and behavior of a system are derived from its parts, from interactions between those parts, and from interactions with other systems (Hitchins 2009 p. 60).

Layer Hierarchy	The evolution of complex systems is facilitated by their hierarchical structure (including stable intermediate forms) and the understanding of complex systems is facilitated by their hierarchical description (Pattee 1973; Bertalanffy 1968; Simon 1996).
Leverage	Achieve maximum leverage (Hybertson 2009). Because of the power versus generality tradeoff, leverage can be achieved by a complete solution (power) for a narrow class of problems, or by a partial solution for a broad class of problems (generality).
Modularity	Unrelated parts of the system should be separated, and related parts of the system should be grouped together (Griswold 1995; Wikipedia 2012a).
Network	The network is a fundamental topology for systems that forms the basis of togetherness, connection, and dynamic interaction of parts that yield the behavior of complex systems (Lawson 2010; Martin et al. 2004; Sillitto 2010).
Parsimony	One should choose the simplest explanation of a phenomenon, the one that requires the fewest assumptions (Cybernetics 2012). This applies not only to choosing a design, but also to operations and requirements.
Regularity	Systems science should find and capture regularities in systems, because those regularities promote systems understanding and facilitate systems practice (Bertalanffy 1968).
Relations	A system is characterized by its relations: the interconnections between the elements. Feedback is a type of relation. The set of relations defines the network of the system (Odum 1994).
Separation of Concerns	A larger problem is more effectively solved when decomposed into a set of smaller problems or concerns (Erl 2012; Greer 2008).
Similarity/Difference	Both the similarities and differences in systems should be recognized and accepted for what they are (Bertalanffy 1975 p. 75; Hybertson 2009). Avoid forcing one size fits all, and avoid treating everything as entirely unique.
Stability/Change	Things change at different rates, and entities or concepts at the stable end of the spectrum can and should be used to provide a guiding context for rapidly changing entities at the volatile end of the spectrum (Hybertson 2009). The study of complex adaptive systems can give guidance to system behavior and design in changing environments (Holland 1992).
Synthesis	Systems can be created by "choosing (conceiving, designing, selecting) the right parts, bringing them together to interact in the right way, and in orchestrating those interactions to create requisite properties of the whole, such that it performs with optimum effectiveness in its operational environment, so solving the problem that prompted its creation" (Hitchins 2009: 120).
View	Multiple views, each based on a system aspect or concern, are essential to understand a complex system or problem situation. One critical view is how concern relates to properties of the whole (Edson 2008; Hybertson 2009).

The principles are not independent. They have synergies and tradeoffs. Lipson (2007), for example, argued that "scalability of open-ended evolutionary processes depends on their ability to exploit functional modularity, structural regularity and hierarchy." He proposed a formal model for examining the properties, dependencies, and tradeoffs among these principles. Edson (2008) related many of the above principles in a structure called the conceptagon, which he modified from the work of Boardman and Sauser (2008). Edson also provided guidance on how to apply these principles. Not all principles apply to every system or engineering decision. Judgment, experience, and heuristics (see below) provide understanding into which principles apply in a given situation.

Several principles illustrate the relation of view with the dualism and yin yang principle, for example, holism and separation of concerns. These principles appear to be contradictory but are in fact dual ways of dealing with complexity. Holism deals with complexity by focusing on the whole system, while separation of concerns divides a problem or system into smaller, more manageable elements that focus on particular concerns. They are reconciled by the fact that both views are needed to understand systems and to engineer systems; focusing on only one or the other does not give sufficient understanding or a good overall solution. This dualism is closely related to the systems thinking paradox described in What is Systems Thinking?.

Rosen (1979) discussed "false dualisms" of systems paradigms that are considered incompatible but are in fact different aspects or views of reality. In the present context, they are thus reconcilable through yin yang harmonization. Edson (2008) emphasized viewpoints as an essential principle of systems thinking; specifically, as a way to understand opposing concepts.

Derick Hitchins (2003) produced a systems life cycle theory described by a set of seven principles forming an integrated set. This theory describes the creation, manipulation and demise of engineered systems. These principles consider the factors which contribute to the stability and survival of man made systems in an environment. Stability is associated with the principle of **connected variety**, in which stability is increased by variety, plus the **cohesion** and **adaptability** of that variety. Stability is limited by allowable relations, resistance to change, and patterns of interaction. Hitchins describes how interconnected systems tend toward a **cyclic progression**, in which variety is generated, dominance emerges to suppress variety, dominant modes decay and collapse and survivors emerge to generate new variety.

Guidance on how to apply many of these principles to engineered systems is given in the topic Synthesizing Possible Solutions, as well as in System Definition and other knowledge areas in Part 3 of the SEBoK.

Prerequisite Laws of Design Science

John Warfield (1994) identified a set of laws of generic design science that are related to systems principles. Three of these laws are stated here:

1. "Law of Requisite Variety": A design situation embodies a variety that must be matched by the specifications. The variety includes the diversity of stakeholders. This law is an application of the design science of the Ashby (1956) Law of Requisite Variety, which was defined in the context of cybernetics and states that to successfully regulate a system, the variety of the regulator must be at least as large as the variety of the regulated system.
2. "Law of Requisite Parsimony": Information must be organized and presented in a way that prevents human information overload. This law derives from Miller's findings on the limits of human information processing capacity (Miller 1956). Warfield's structured dialog method is one possible way to help achieve the requisite parsimony.
3. "Law of Gradation": Any conceptual body of knowledge can be graded in stages or varying degrees of complexity and scale, ranging from simplest to most comprehensive, and the degree of knowledge applied to any design situation should match the complexity and scale of the situation. A corollary, called the Law of Diminishing Returns, states that a body of knowledge should be applied to a design situation at the stage at which the point of diminishing returns is reached.

Heuristics and Pragmatic Principles

A heuristic is a common sense rule intended to increase the probability of solving some problem (WordWeb 2012b). In the present context, it may be regarded as an informal or pragmatic principle. Maier and Rechtin (2000) identified an extensive set of heuristics that are related to systems principles. A few of these heuristics are stated here:

- Relationships among the elements are what give systems their added value. This is related to the "Interaction" principle.
- Efficiency is inversely proportional to universality. This is related to the "Leverage" principle.
- The first line of defense against complexity is simplicity of design. This is related to the "Parsimony" principle.
- In order to understand anything, you must not try to understand everything (attributed to Aristotle). This is related to the "Abstraction" principle.

An International Council on Systems Engineering (INCOSE) working group (INCOSE 1993) defined a set of "pragmatic principles" for systems engineering (SE). They are essentially best practice heuristics for engineering a system. For example:

- Know the problem, the customer, and the consumer
- Identify and assess alternatives to converge on a solution
- Maintain the integrity of the system

Hitchins defines a set of SE principles which include principles of holism and synthesis as discussed above, as well as principles describing how systems problems that are of particular relevance to a Systems Approach Applied to

Engineered Systems should be resolved (Hitchins 2009).

Patterns of Systems Thinking

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Scott Jackson, Janet Singer, and Duane Hybertson

-

This topic forms part of the Systems Thinking knowledge area (KA). It identifies systems patterns as part of the basic ideas of systems thinking. The general idea of patterns and a number of examples are described. A brief conclusion discusses the maturity of systems science from the perspective of principles and patterns.

Systems Patterns

This section first discusses definitions, types, and pervasiveness of patterns. Next, samples of basic patterns in the form of hierarchy and network patterns, metapatterns, and systems engineering (SE) patterns are discussed. Then samples of patterns of failure (or “antipatterns”) are presented in the form of system archetypes, along with antipatterns in software engineering and other fields. Finally, a brief discussion of patterns as maturity indicators is given.

Pattern Definitions and Types

The most general definition of pattern is that it is an expression of an observed regularity. Patterns exist in both natural and artificial systems and are used in both systems science and systems engineering (SE). Theories in science are patterns. Building architecture styles are patterns. Engineering uses patterns extensively.

Patterns are a representation of similarities in a set or class of problems, solutions or systems. In addition, some patterns can also represent uniqueness or differences, e.g., uniqueness pattern or unique identifier, such as automobile vehicle identification number (VIN), serial number on a consumer product, human fingerprints, DNA. The pattern is that a unique identifier, common to all instances in a class (such as a fingerprint), distinguishes between all instances in that class.

The term pattern has been used primarily in building architecture and urban planning (Alexander et al. 1977, Alexander 1979) and in software engineering (e.g., Gamma et al. 1995; Buschmann et al. 1996). Their definitions portray a pattern as capturing design ideas as an archetypal and reusable description. A design pattern provides a generalized solution in the form of templates to a commonly occurring real-world problem within a given context. A design pattern is not a finished design that can be transformed directly into a specific solution. It is a description or template for how to solve a problem that can be used in many different specific situations (Gamma et al. 1995; Wikipedia 2012b). Alexander placed significant emphasis on the pattern role of reconciling and resolving competing forces, which is an important application of the yin yang principle.

Other examples of general patterns in both natural and engineered systems include: conventional designs in engineering handbooks, complex system models such as evolution and predator-prey models that apply to multiple application domains, domain taxonomies, architecture frameworks, standards, templates, architecture styles, reference architectures, product lines, abstract data types, and classes in class hierarchies (Hybertson 2009). Shaw and Garlan (Garlan 1996) used the terms *pattern* and *style* interchangeably in discussing software architecture. Lehmann and Belady (Lehmann 1985) examined a set of engineered software systems and tracked their change over time and observed regularities that they captured as evolution laws or patterns.

Patterns have been combined with model-based systems engineering (MBSE) to lead to pattern-based systems engineering (PBSE) (Schindel and Smith 2002, Schindel 2005).

Patterns also exist in systems practice, both science and engineering. At the highest level, Gregory (1966) defined science and design as behavior patterns:

> *The scientific method is a pattern of problem-solving behavior employed in finding out the nature of what exists, whereas the design method is a pattern of behavior employed in inventing things of value which do not yet exist.*

Regularities exist not only as positive solutions to recurring problems, but also as patterns of failure, i.e., as commonly attempted solutions that consistently fail to solve recurring problems. In software engineering these are called antipatterns, originally coined and defined by Koenig (1995). An antipattern is just like a pattern, except that instead of a solution it gives something that looks superficially like a solution but isn't one. Koenig's rationale was that if one does not know how to solve a problem, it may nevertheless be useful to know about likely blind alleys. Antipatterns may include patterns of pathologies (i.e., common diseases), common impairment of normal functioning, and basic recurring problematic situations. These antipatterns can be used to help identify the root cause of a problem and eventually lead to solution patterns. The concept was expanded beyond software to include project management, organization, and other antipatterns (Brown et al. 1998; AntiPatterns Catalog 2012).

Patterns are grouped in the remainder of this section into basic foundational patterns and antipatterns (or patterns of failure).

Basic Foundational Patterns

The basic patterns in this section consist of a set of hierarchy and network patterns, followed by a set of metapatterns and SE patterns.

Hierarchy and Network Patterns

The first group of patterns are representative types of hierarchy patterns distinguished by the one-to-many relation type (extended from Hybertson 2009, 90), as shown in the table below. These are presented first because hierarchy patterns infuse many of the other patterns discussed in this section.

Table 1. Hierarchy Patterns. (SEBoK Original)

Relation	Hierarchy Type or Pattern
Basic: Repeating One-to-Many Relation	General: Tree structure
Part of a Whole	Composition (or Aggregation) hierarchy
Part of + Dualism: Each element in the hierarchy is a holon, i.e., is both a whole that has parts and a part of a larger whole	Holarchy (composition hierarchy of holons) (Koestler 1967) - helps recognize similarities across levels in multi-level systems
Part of + Interchangeability: The parts are clonons, i.e., interchangeable	Composition Hierarchy of Clonons (Bloom 2005). Note: This pattern reflects horizontal similarity.
Part of + Self-Similarity: At each level, the shape or structure of the whole is repeated in the parts, i.e., the hierarchy is self-similar at all scales.	Fractal. Note: This pattern reflects vertical similarity.
Part of + Connections or Interactions among Parts	System composition hierarchy
Control of Many by One	Control hierarchy—e.g., a command structure
Subtype or Sub-Class	Type or specialization hierarchy; a type of generalization
Instance of Category	Categorization (object-class; model-metamodel…) hierarchy; a type of generalization

Network patterns are of two flavors. First, traditional patterns are network topology types, such as bus (common backbone), ring, star (central hub), tree, and mesh (multiple routes) (ATIS 2008). Second, the relatively young science of networks has been investigating social and other complex patterns, such as percolation, cascades, power law, scale-free, small worlds, semantic networks, and neural networks (Boccara 2004; Neumann et al. 2006).

Metapatterns

The metapatterns identified and defined in the table below are from (Bloom 2005), (Volk and Bloom 2007), and (Kappraff 1991). They describe a metapattern as convergences exhibited in the similar structures of evolved systems across widely separated scales (Volk and Bloom 2007).

Table 2. Metapatterns. (SEBoK Original)

Name	Brief Definition	Examples
Spheres	Shape of maximum volume, minimum surface, containment	Cell, planet, dome, ecosystem, community
Centers	Key components of system stability	Prototypes, purpose, causation; Deoxyribonucleic acid (DNA), social insect centers, political constitutions and government, attractors
Tubes	Surface transfer, connection, support	Networks, lattices, conduits, relations; leaf veins, highways, chains of command
Binaries Plus	Minimal and thus efficient system	Contrast, duality, reflections, tensions, complementary/symmetrical/reciprocal relationships; two sexes, two-party politics, bifurcating decision process
Clusters, Clustering	Subset of webs, distributed systems of parts with mutual attractions	Bird flocks, ungulate herds, children playing, egalitarian social groups
Webs or Networks	Parts in relationships within systems (can be centered or clustered, using clonons or holons)	Subsystems of cells, organisms, ecosystems, machines, society
Sheets	Transfer surface for matter, energy, or information	Films; fish gills, solar collectors
Borders and Pores	Protection, openings for controlled exchange	Boundaries, containers, partitions, cell membranes, national borders
Layers	Combination of other patterns that builds up order, structure, and stabilization	Levels of scale, parts and wholes, packing, proportions, tiling

Similarity	Figures of the same shape but different sizes	Similar triangles, infant-adult
Emergence	General phenomenon when a new type of functionality derives from binaries or webs.	Creation (birth), life from molecules, cognition from neurons
Holarchies	Levels of webs, in which successive systems are parts of larger systems	Biological nesting from biomolecules to ecosystems, human social nesting, engineering designs, computer software
Holons	Parts of systems as functionally unique	Heart-lungs-liver (holons) of body
Clonons	Parts of systems as interchangeable	Skin cells (clonons) of the skin; bricks in constructing a house
Arrows	Stability or gradient-like change over time	Stages, sequence, orientation, stress, growth, meanders, biological homeostasis, growth, self-maintaining social structures
Cycles	Recurrent patterns in systems over time	Alternating repetition, vortex, spiral, turbulence, helices, rotations; protein degradation and synthesis, life cycles, power cycles of electricity generating plants, feedback cycles
Breaks	Relatively sudden changes in system behavior	Transformation, change, branching, explosion, cracking, translations; cell division, insect metamorphosis, coming-of-age ceremonies, political elections, bifurcation points
Triggers	Initiating agents of breaks, both internal and external	Sperm entering egg or precipitating events of war
Gradients	Continuum of variation between binary poles	Chemical waves in cell development, human quantitative and qualitative values

Systems Engineering Patterns

Some work has been done on various aspects of explicitly applying patterns to SE. A review article of much of this work was written by Bagnulo and Addison (2010), covering patterns in general, capability engineering, pattern languages, pattern modeling, and other SE-related pattern topics. Cloutier (2005) discussed applying patterns to SE, based on architecture and software design patterns. Haskins (2005), and Simpson and Simpson (2006) discussed the use of SE pattern languages to enhance the adoption and use of SE patterns. Simpsons identified three high-level, global patterns that can be used as a means of organizing systems patterns:

- Anything can be described as a system.
- The problem system is always separate from the solution system.
- Three systems, at a minimum, are always involved in any system activity: the environmental system, the product system, and the process system.

Haskins (2008) also proposed the use of patterns as a way to facilitate the extension of SE from traditional technological systems to address social and socio-technical systems. Some patterns have been applied and identified in this extended arena, described as patterns of success by Rebovich and DeRosa (2012). Stevens (2010) also discussed patterns in the engineering of large-scale, complex “mega-systems.”

A common SE activity in which patterns are applied is in system design, especially in defining one or more solution options for a system-of-interest. See Synthesizing Possible Solutions for a discussion. The more specific topic of using patterns (and antipatterns, as described below) to understand and exploit emergence is discussed in the Emergence topic.

Patterns of Failure: Antipatterns

System Archetypes

The system dynamics community has developed a collection of what are called system archetypes. The concept was originated by Forrester (1969), while Senge (1990) appears to have introduced the system archetype term. According to Braun (2002), the archetypes describe common patterns of behavior that help answer the question, "Why do we keep seeing the same problems recur over time?" They focus on behavior in organizations and other complex social systems that are repeatedly but unsuccessfully used to solve recurring problems. This is why they are grouped here under antipatterns, even though the system dynamics community does not refer to the archetypes as antipatterns. The table below summarizes the archetypes. There is not a fixed set, or even fixed names for a given archetype. The table shows alternative names for some archetypes.

Table 3. System Archetypes. (SEBoK Original)

Name (Alternates)	Description	Reference**
Counterintuitive Behavior	Forrester identified three "especially dangerous" counter-intuitive behaviors of social systems, which correspond respectively to three of the archetypes discussed below: (1) Low-Leverage Policies: Ineffective Actions; (2) High Leverage Policies: Often Wrongly Applied; and (3) Long-Term vs. Short-Term Trade-offs	F1, F2
Low-Leverage Policies: Ineffective Actions (Policy Resistance)	Most intuitive policy changes in a complex system have very little leverage to create change; this is because the change causes reactions in other parts of the system that counteract the new policy.	F1, F3, M
High Leverage Policies: Often Wrongly Applied (High Leverage, Wrong Direction)	A system problem is often correctable with a small change, but this high-leverage solution is typically counter-intuitive in two ways: (1) the leverage point is difficult to find because it is usually far removed in time and place from where the problem appears, and (2) if the leverage point is identified, the change is typically made in the wrong direction, thereby intensifying the problem.	F1, F3, M
Long-Term vs. Short-Term Trade-offs (Fixes that Fail, Shifting the Burden, Addiction)	Short-term solutions are intuitive, but in complex systems there is nearly always a conflict or tradeoff between short-term and long-term goals. Thus, a quick fix produces immediate positive results, but its unforeseen and unintended long-term consequences worsen the problem. Furthermore, a repeated quick fix approach makes it harder to change to a more fundamental solution approach later.	F1, F3, M, S, B
Drift to Low Performance (Eroding Goals, Collapse of Goals)	There is a strong tendency for complex system goals to drift downward. A gap between current state and goal state creates pressure to lower the goal rather than taking difficult corrective action to reach the goal. Over time the continually lowered goals lead to crisis and possible collapse of the system.	F1, F3, M, B
Official Addiction – Shifting the Burden to the Intervener	The ability of a system to maintain itself deteriorates when an intervener provides help and the system then becomes dependent on the intervener.	M, S
Limits to Growth (a.k.a. Limits to Success)	A reinforcing process of accelerating growth (or expansion) will encounter a balancing process as the limit of that system is approached and continuing efforts will produce diminishing returns as one approaches the limits.	S, B
Balancing Process with Delay	Delay in the response of a system to corrective action causes the correcting agent to either over-correct or to give up due to no visible progress.	S
Escalation	Two systems compete for superiority, with each escalating its competitive actions to get ahead, to the point that both systems are harmed.	B
Success to the Successful	Growth leads to decline elsewhere. When two equally capable systems compete for a limited resource, if one system receives more resources, it is more likely to be successful, which results in its receiving even more resources, in a reinforcing loop.	S, B
Tragedy of the Commons	A shared resource is depleted as each system abuses it for individual gain, ultimately hurting all who share it.	H, S, B

Growth and Underinvestment	In a situation where capacity investments can overcome limits, if such investments are not made, then growth stalls, which then rationalizes further underinvestment.	S, B
Accidental Adversaries	Two systems destroy their relationship through escalating retaliations for perceived injuries.	B
Attractiveness Principle	In situations where a system faces multiple limiting or impeding factors, the tendency is to consider each factor separately to select which one to address first, rather than a strategy based on the interdependencies among the factors.	B

** **B—**(Braun 2002); **F1—**(Forrester 1969); **F2—**(Forrester 1995); **F3—**(Forrester 2009); **H—**(Hardin 1968); **M—**(Meadows 1982); **S—**(Senge 1990).

Relations among system archetypes were defined by Goodman and Kleiner (1993/1994) and republished in Senge et al. (1994).

Software and Other Antipatterns

Antipatterns have been identified and collected in the software community in areas that include: architecture, development, project management, user interface, organization, analysis, software design, programming, methodology, and configuration management (AntiPatterns Catalog 2012, Wikibooks 2012). A brief statement of three of them follows; the first two are organization and the third is software design.

- Escalation of commitment - Failing to revoke a decision when it proves wrong.
- Moral hazard - Insulating a decision-maker from the consequences of his or her decision.
- Big ball of mud - A system with no recognizable structure.

A link between the software community and the system archetypes is represented in a project at the Software Engineering Institute (SEI) (2012), which explores the system archetypes in the context of identifying recurring software acquisition problems as "acquisition archetypes." They refer to both types of archetypes as patterns of failure.

Another set of antipatterns in the general systems arena has been compiled by Troncale (2010; 2011) in his systems pathologies project. Sample pathology types or patterns include:

- Cyberpathologies - Systems-level malfunctions in feedback architectures.
- Nexopathologies - Systems-level malfunctions in network architectures or dynamics.
- Heteropathologies - Systems-level malfunctions in hierarchical, modular structure & dynamics.

Some treatments of antipatterns, including Senge (1990) and SEI (2012), also provide some advice on dealing with or preventing the antipattern.

Patterns and Maturity

Patterns may be used as an indicator of the maturity of a domain of inquiry, such as systems science or systems engineering. In a mature and relatively stable domain, the problems and solutions are generally understood and their similarities are captured in a variety of what are here called patterns. A couple of observations can be made in this regard on the maturity of systems science in support of systems engineering.

In the arenas of physical systems and technical systems, systems science is relatively mature; many system patterns of both natural physical systems and engineered technical systems are reasonably well defined and understood.

In the arena of more complex systems, including social systems, systems science is somewhat less mature. Solution patterns in that arena are more challenging. A pessimistic view of the possibility of science developing solutions to social problems was expressed by Rittel and Webber (1973) in their classic paper on wicked problems: "The search for scientific bases for confronting problems of social policy is bound to fail, because . . . they are 'wicked' problems, whereas science has developed to deal with 'tame' problems." A more optimistic stance toward social problems has characterized the system dynamics community. They have been pointing out for over 40 years the problems with conventional solutions to social problems, in the form of the system archetypes and associated feedback loop

models. That was an important first step. Nevertheless, they have had difficulty achieving the second step; producing social patterns that can be applied to solve those problems. The antipatterns characterize problems, but the patterns for solving those problems are elusive.

Despite the difficulties, however, social systems do exhibit regularities, and social problems are often solved to some degree. The social sciences and complex systems community have limited sets of patterns, such as common types of organization structures, common macro-economic models, and even patterns of insurgency and counter-insurgency. The challenge for systems science is to capture those regularities and the salient features of those solutions more broadly and make them explicit and available in the form of mature patterns. Then perhaps social problems can be solved on a more regular basis. As systems engineering expands its scope from the traditional emphasis on technical aspects of systems to the interplay of the social and technical aspects of socio-technical systems, such progress in systems science is becoming even more important to the practice of systems engineering.

-

A model is a simplified representation of a system at some particular point in time or space intended to promote understanding of the real system. As an abstraction of a system, it offers insight about one or more of the system's aspects, such as its function, structure, properties, performance, behavior, or cost.

Overview

The modeling of systems as holistic, value-providing entities has been gaining recognition as a central process of systems engineering. The use of modeling and simulation during the early stages of the system design of complex systems and architectures can:

- document system functions and requirements,
- assess the mission performance,
- estimate costs,
- evaluate tradeoffs, and
- provide insights to improve performance, reduce risk, and manage costs.

Modeling and analysis can complement testing and evaluations which occur later in the life cycle. In some systems, modeling and simulation may be the only way to fully evaluate performance (e.g., ballistic missile defense) or to evaluate system performance in severe scenarios (e.g., response to weapons of mass destruction attacks on the homeland). Furthermore, advanced simulations, e.g. flight simulators, and command and control center simulations, can be a cost-effective technique for personnel training in accompaniment with operational system training (INCOSE 2012).

Modeling serves to make concepts concrete and formal, enhance quality, productivity, documentation, and innovation, as well as to reduce the cost and risk of systems development.

Modeling occurs at many levels: component, subsystem, system, and systems-of-systems; and throughout the life cycle of a system. Different types of models may be needed to represent systems in support of the analysis, specification, design, and verification of systems. This knowledge area provides an overview of models used to

represent different aspects of systems.

Modeling is a common practice that is shared by most engineering disciplines, including:

- electrical engineering, which uses electrical circuit design models
- mechanical engineering, which uses three-dimensional computer-aided design models
- software engineering, which uses software design and architecture models.

Each of these disciplines has its own language with its syntax and semantics, serving as a means of communication among professionals in that discipline. Analytic models are used to support power, thermal, structural, and embedded real-time analysis.

Modeling Standards play an important role in defining system modeling concepts that can be represented for a particular domain of interest and enable the integration of different types of models across domains of interest.

Topics

Each part of the Guide to the Systems Engineering Body of Knowledge (SEBoK) is divided into knowledge areas (KAs), which are groupings of information with a related theme. The KAs, in turn, are divided into topics. This KA contains the following topics:

- What is a Model?
- Why Model?
- Types of Models
- System Modeling Concepts
- Integrating Supporting Aspects into System Models
- Modeling Standards

What is a Model?

- Lead Author:
- Sanford Friedenthal
- Contributing Authors:
- Dov Dori and Yaniv Mordecai

-

This topic provides foundational concepts, such as definitions of a model and a modeling language, and expresses their relationships to modeling tools and model-based systems engineering (MBSE).

Definition of a Model

There are many definitions of the word *model*. The following definitions refer to a model as a representation of selected aspects of a domain of interest to the modeler:

- a physical, mathematical, or otherwise logical representation of a system, entity, phenomenon, or process (DoD 1998);
- a representation of one or more concepts that may be realized in the physical world (Friedenthal, Moore, and Steiner 2009);
- a simplified representation of a system at some particular point in time or space intended to promote understanding of the real system (Bellinger 2004);
- an abstraction of a system, aimed at understanding, communicating, explaining, or designing aspects of interest of that system (Dori 2002); and
- a selective representation of some system whose form and content are chosen based on a specific set of concerns; the model is related to the system by an explicit or implicit mapping (Object Management Group 2010).

In the context of systems engineering, a model that represents a system and its environment is of particular importance to the system engineer who must specify, design, analyze, and verify systems, as well as share information with other stakeholders. A variety of system models are used to represent different engineered systems for different modeling purposes. Some of the purposes for modeling systems are summarized in the topic Why Model?, and a simple taxonomy of the different types of models are described in the topic Types of Models. The modeling standards topic refers to some of the standard system modeling languages and other modeling standards that support MBSE.

A model can have different forms as indicated in the first definition above, including a physical, mathematical, or logical representation. A physical model can be a mockup that represents an actual system, such as a model airplane. A mathematical model may represent possible flight trajectories in terms of acceleration, speed, position, and orientation. A logical model may represent logical relationships that describe potential causes of airplane failure, such as how an engine failure can result in a loss of power and cause the airplane to lose altitude, or how the parts of

the system are interconnected. It is apparent that many different models may be required to represent a system-of-interest (SoI).

Modeling Language

A physical model is a concrete representation of an actual system that can be felt and touched. Other models may be more abstract representations of a system or entity. These models rely on a modeling language to express their meaning as explained in "On Ontology, Ontologies, Conceptualizations, Modeling Languages, and (Meta)Models" (Guizzardi 2007).

Just as engineering drawings express the 3D structure of mechanical and architectural designs, conceptual models are the means by which systems are conceived, architected, designed, and built. The resulting models are the counterparts of the mechanical design blueprint. However, the difference is that, while blueprints are exact representations of physical artifacts with a precise, agreed-upon syntax and long tradition of serving as a means of communication among professionals, conceptual models are just beginning to make headway toward being a complete and unambiguous representation of a system under development. The articles in the special section of Communications of the Association for Computing Machinery (ACM) (Dori 2003) present the abstract world of systems analysis and architecting by means of conceptual modeling, and how to evaluate, select, and construct models.

Modeling languages are generally intended to be both human-interpretable and computer-interpretable, and are specified in terms of both syntax and semantics.

The abstract syntax specifies the model constructs and the rules for constructing the model. In the case of a natural language like English, the constructs may include types of words such as verbs, nouns, adjectives, and prepositions, and the rules specify how these words can be used together to form proper sentences. The abstract syntax for a mathematical model may specify constructs to define mathematical functions, variables, and their relationships. The abstract syntax for a logical model may also specify constructs to define logical entities and their relationships. A well-formed model abides by the rules of construction, just as a well-formed sentence must conform to the grammatical rules of the natural language.

The concrete syntax specifies the symbols used to express the model constructs. The natural language English can be expressed in text or Morse code. A modeling language may be expressed using graphical symbols and/or text statements. For example, a functional flow model may be expressed using graphical symbols consisting of a combination of graphical nodes and arcs annotated with text, while a simulation modeling language may be expressed using a programming language text syntax such as the C programming language.

The semantics of a language define the meaning of the constructs. For example, an English word does not have explicit meaning until the word is defined. Similarly, a construct that is expressed as a symbol, such as a box or arrow on a flow chart, does not have meaning until it is defined. The language must give meaning to the concept of a verb or noun, and must give specific meaning to a specific word that is a verb or noun. The definition can be established by providing a natural language definition or by mapping the construct to a formalism whose meaning is defined. As an example, a graphical symbol that expresses $sin(x)$ and $cos(x)$ is defined using a well-defined mathematical formalism for the sine and cosine function. If the position of a pendulum is defined in terms of $sin(\theta)$ and $cos(\theta)$, the meaning of the pendulum position is understood in terms of these formalisms.

Modeling Tools

Models are created by a modeler using modeling tools. For physical models, the modeling tools may include drills, lathes, and hammers. For more abstract models, the modeling tools are typically software programs running on a computer. These programs provide the ability to express modeling constructs using a particular modeling language. A word processor can be viewed as a tool used to build text descriptions using natural language. In a similar way, modeling tools are used to build models using modeling languages. The tool often provides a tool palette to select symbols and a content area to construct the model from the graphical symbols or other concrete syntax. A modeling tool typically checks the model to evaluate whether it conforms to the rules of the language and enforces such rules to help the modeler create a well-formed model. This is similar to the way a word processor checks the text to see that it conforms to the grammar rules for the natural language.

Some modeling tools are commercially available products, while others may be created or customized to provide unique modeling solutions. Modeling tools are often used as part of a broader set of engineering tools which constitute the systems development environment. There is increased emphasis on tool support for standard modeling languages that enable models and modeling information to be interchanged among different tools.

Relationship of Model to Model-Based Systems Engineering

The International Council of Systems Engineering (INCOSE) (INCOSE Systems Engineering Vision 2020 2007) defines MBSE as "the formalized application of modeling to support system requirements, design, analysis, verification, and validation activities beginning in the conceptual design phase and continuing throughout development and later life cycle phases." In MBSE, the models of the system are primary artifacts of the systems engineering process, and are managed, controlled, and integrated with other parts of the system technical baseline. This contrasts with the traditional document-centric approach to systems engineering, where text-based documentation and specifications are managed and controlled. Leveraging a model-based approach to systems engineering is intended to result in significant improvements in system specification and design quality, lower risk and cost of system development by surfacing issues early in the design process, enhanced productivity through reuse of system artifacts, and improved communications among the system development and implementation teams.

In addition to creating models, the MBSE approach typically includes methods for model management, which aim to ensure that models are properly controlled, and methods for model validation, which aim to ensure that models accurately represent the systems being modeled.

The jointly sponsored INCOSE/Object Management Group (OMG) MBSE Wiki [1] provides additional information on the INCOSE MBSE Initiative, including some applications of MBSE and some key topics related to MBSE such as sections on Methodology and Metrics, and Model Management.

The Final Report of the Model Based Engineering (MBE) Subcommittee, which was generated by the the National Defense Industrial Association (NDIA) Modeling and Simulation Committee of the Systems Engineering Division, highlights many of the benefits, risks, and challenges of a model-based approach, and includes many references to case studies of MBE (NDIA 2011).

Brief History of System Modeling Languages and Methods

Many system modeling methods and associated modeling languages have been developed and deployed to support various aspects of system analysis, design, and implementation. Functional modeling languages include the data flow diagram (DFD) (Yourdon and Constantine 1979), Integration Definition for Functional Modeling (IDEF0) (Menzel and Maier 1998), and enhanced functional flow block diagram (eFFBD). Other behavioral modeling techniques include the classical state transition diagram, statecharts (Harel 1987), and process flow diagrams. Structural modeling techniques include data structure diagrams (Jackson 1975), entity relationship diagrams (Chen 1976), and object modeling techniques (Rumbaugh et al. 1991), which combine object diagrams, DFDs, and statecharts.

In 2008, Estefan conducted an extensive survey of system modeling methods, processes, and tools and documented the results in A Survey of Model-Based Systems Engineering (MBSE) Methodologies (Estefan 2008). This survey identifies several candidate MBSE methodologies and modeling languages that can be applied to support an MBSE approach. Additional modeling methods are available from the MBSE Wiki [1] under the section on Methodology and Metrics [2]. The modeling standards section refers to some of the standard system modeling languages and other modeling standards that support MBSE. Since Estefan's report, a number of surveys have been conducted to understand the acceptance and barriers to model-based systems engineering (Bone and Cloutier 2010, 2014; Cloutier 2015).

-

System models can be used for many purposes. This topic highlights some of those purposes, and provides indicators of an effective model in the context of model-based systems engineering (MBSE).

Purpose of a Model

Models are representations that can aid in defining, analyzing, and communicating a set of concepts. System models are specifically developed to support analysis, specification, design, verification, and validation of a system, as well as to communicate certain information. One of the first principles of modeling is to clearly define the purpose of the model. Some of the purposes that models can serve throughout the system life cycle are:

- **Characterizing an existing system:** Many existing systems are poorly documented and modeling the system can provide a concise way to capture the existing system design. This information can then be used to facilitate system maintenance or to assess the system with the goal of improving it. This is analogous to creating an architectural model of an old building with overlays for electrical, plumbing, and structure before proceeding to upgrade it to new standards to withstand earthquakes.
- **Mission and system concept formulation and evaluation:** Models can be applied early in the system life cycle to synthesize and evaluate alternative mission and system concepts. This includes clearly and unambiguously defining the system's mission and the value it is expected to deliver to its beneficiaries. Models can be used to explore a trade-space by modeling alternative system designs and assessing the impact of critical system parameters such as weight, speed, accuracy, reliability, and cost on the overall measures of merit. In addition to bounding the system design parameters, models can also be used to validate that the system requirements meet stakeholder needs before proceeding with later life cycle activities such as synthesizing the detailed system design.
- **System design synthesis and requirements flowdown:** Models can be used to support architecting system solutions, as well as flow mission and system requirements down to system components. Different models may be required to address different aspects of the system design and respond to the broad range of system requirements. This may include models that specify functional, interface, performance, and physical requirements, as well as other non-functional requirements such as reliability, maintainability, safety, and security.
- **Support for system integration and verification:** Models can be used to support integration of the hardware and software components into a system, as well as to support verification that the system satisfies its requirements. This often involves integrating lower level hardware and software design models with system-level design models which verify that system requirements are satisfied. System integration and verification may also include replacing selected hardware and design models with actual hardware and software products in order to incrementally verify that system requirements are satisfied. This is referred to as hardware-in-the-loop testing and software-in-the-loop testing. Models can also be used to define the test cases (glossary) and other aspects of the test program to assist in test planning and execution.
- **Support for training:** Models can be used to simulate various aspects of the system to help train users to interact with the system. Users may be operators, maintainers, or other stakeholders. Models may be a basis for developing a simulator of the system with varying degrees of fidelity to represent user interaction in different usage scenarios.

- **Knowledge capture and system design evolution:** Models can provide an effective means for capturing knowledge about the system and retaining it as part of organizational knowledge. This knowledge, which can be reused and evolved, provides a basis for supporting the evolution of the system, such as changing system requirements in the face of emerging, relevant technologies, new applications, and new customers. Models can also enable the capture of families of products.

Indicators of an Effective Model

When modeling is done well, a model's purposes are clear and well-defined. The value of a model can be assessed in terms of how effectively it supports those purposes. The remainder of this section and the topics Types of Models, System Modeling Concepts, and Modeling Standards describe indicators of an effective model (Friedenthal, Moore, and Steiner 2012).

Model Scope

The model must be scoped to address its intended purpose. In particular, the types of models and associated modeling languages selected must support the specific needs to be met. For example, suppose models are constructed to support an aircraft's development. A system architecture model may describe the interconnection among the airplane parts, a trajectory analysis model may analyze the airplane trajectory, and a fault tree analysis model may assess potential causes of airplane failure.

For each type of model, the appropriate breadth, depth, and fidelity should be determined to address the model's intended purpose. The model breadth reflects the system requirements coverage in terms of the degree to which the model must address the functional, interface, performance, and physical requirements, as well as other non-functional requirements, such as reliability, maintainability, and safety. For an airplane functional model, the model breadth may be required to address some or all of the functional requirements to power up, take off, fly, land, power down, and maintain the aircraft's environment.

The model's depth indicates the coverage of system decomposition from the system context down to the system components. For the airplane example, a model's scope may require it to define the system context, ranging from the aircraft, the control tower, and the physical environment, down to the navigation subsystem and its components, such as the inertial measurement unit; and perhaps down to lower-level parts of the inertial measurement unit.

The model's fidelity indicates the level of detail the model must represent for any given part of the model. For example, a model that specifies the system interfaces may be fairly abstract and represent only the logical information content, such as aircraft status data; or it may be much more detailed to support higher fidelity information, such as the encoding of a message in terms of bits, bytes, and signal characteristics. Fidelity can also refer to the precision of a computational model, such as the time step required for a simulation.

Indicators of Model Quality

The quality of a model should not be confused with the quality of the design that the model represents. For example, one may have a high-quality, computer-aided design model of a chair that accurately represents the design of the chair, yet the design itself may be flawed such that when one sits in the chair, it falls apart. A high quality model should provide a representation sufficient to assist the design team in assessing the quality of the design and uncovering design issues.

Model quality is often assessed in terms of the adherence of the model to modeling guidelines and the degree to which the model addresses its intended purpose. Typical examples of modeling guidelines include naming conventions, application of appropriate model annotations, proper use of modeling constructs, and applying model reuse considerations. Specific guidelines are different for different types of models. For example, the guidelines for developing a geometric model using a computer-aided design tool may include conventions for defining coordinate

systems, dimensioning, and tolerances.

Model-Based Metrics

Models can provide a wealth of information that can be used for both technical and management metrics to assess the modeling effort, and, in some cases, the overall systems engineering (SE) effort. Different types of models provide different types of information. In general, models provide information that enables one to:

- assess progress;
- estimate effort and cost;
- assess technical quality and risk; and
- assess model quality.

Models can capture metrics similar to those captured in a traditional document-based approach to systems engineering, but potentially with more precision given the more accurate nature of models compared to documents. Traditional systems engineering metrics are described in *Metrics Guidebook for Integrated Systems and Product Development* (Wilbur 2005).

A model's progress can be assessed in terms of the completeness of the modeling effort relative to the defined scope of the model. Models may also be used to assess progress in terms of the extent to which the requirements have been satisfied by the design or verified through testing. When augmented with productivity metrics, the model can be used to estimate the cost of performing the required systems engineering effort to deliver the system.

Models can be used to identify critical system parameters and assess technical risks in terms of any uncertainty that lies in those parameters. The models can also be used to provide additional metrics that are associated with its purpose. For example, when the model's purpose is to support mission and system concept formulation and evaluation, then a key metric may be the number of alternative concepts that are explored over a specified period of time.

Types of Models

- Lead Author:
- Sanford Friedenthal
- Contributing Authors:
- Dov Dori and Yaniv Mordecai

-

There are many different types of models expressed in a diverse array of modeling languages and tool sets. This article offers a taxonomy of model types and highlights how different models must work together to support broader engineering efforts.

Model Classification

There are many different types of models and associated modeling languages to address different aspects of a system and different engineered systems. Since different models serve different purposes, a classification of models can be useful for selecting the right type of model for the intended purpose and scope.

Formal versus Informal Models

Since a system model is a representation of a system, many different expressions that vary in degrees of formalism could be considered models. In particular, one could draw a picture of a system and consider it a model. Similarly, one could write a description of a system in text and refer to that as a model. Both examples are representations of a system. However, unless there is some agreement on the meaning of the terms, there is a potential lack of precision and the possibility of ambiguity in the representation.

The primary focus of system modeling is to use models supported by a well-defined modeling language. While less formal representations can be useful, a model must meet certain expectations for it to be considered within the scope of model-based systems engineering (MBSE). In particular, the initial classification distinguishes between informal and formal models as supported by a modeling language with a defined syntax and the semantics for the relevant domain of interest.

Physical Models versus Abstract Models

The United States “Department of Defense Modeling and Simulation (M&S) Glossary” asserts that “a model can be [a] physical, mathematical, or otherwise logical representation of a system” (1998). This definition provides a starting point for a high-level model classification. A physical model is a concrete representation that is distinguished from the mathematical and logical models, both of which are more abstract representations of the system. The abstract model can be further classified as descriptive (similar to logical) or analytical (similar to mathematical). Some example models are shown in Figure 1.

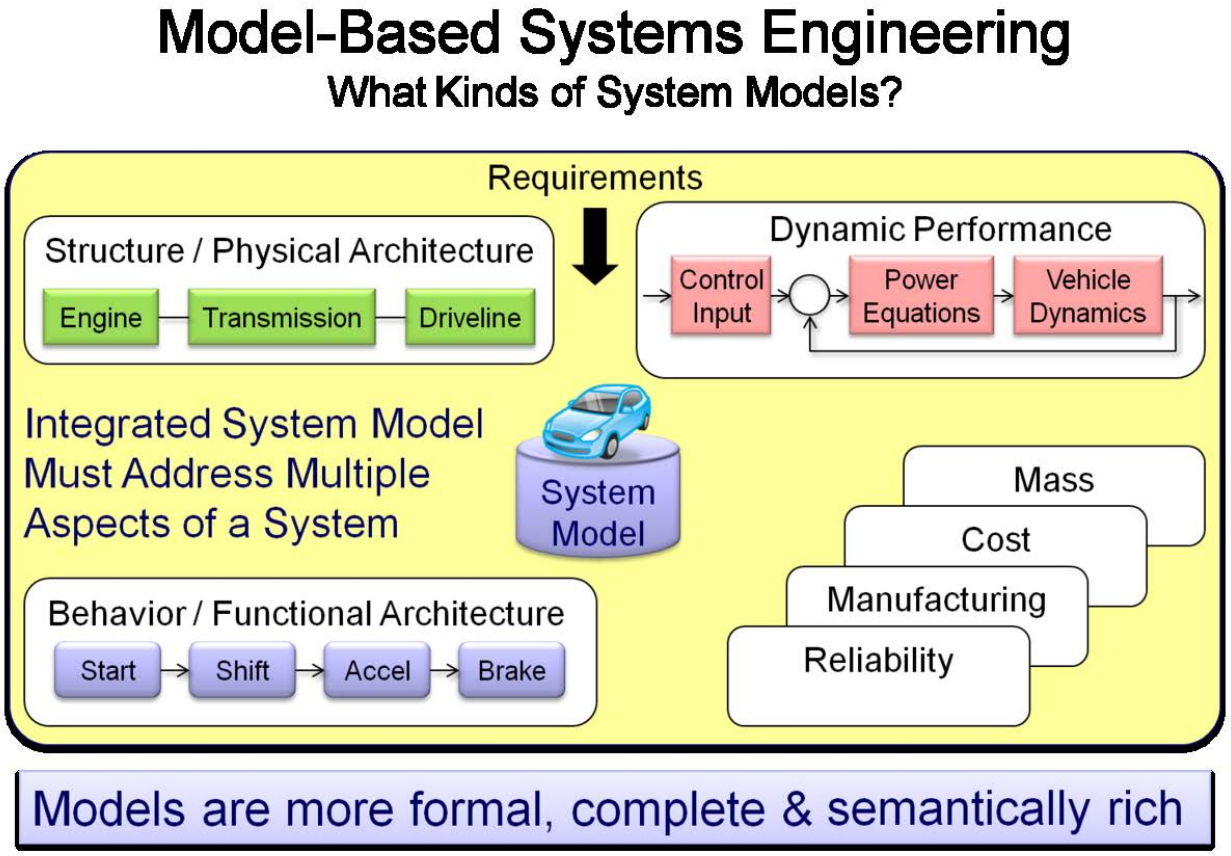

Figure 1. Model-Based Systems Engineering (Paredis 2011). Reprinted with permission of Chris Paredis from Georgia Tech. All other rights are reserved by the copyright owner.

Descriptive Models

A descriptive model describes logical relationships, such as the system's whole-part relationship that defines its parts tree, the interconnection between its parts, the functions that its components perform, or the test cases that are used to verify the system requirements. Typical descriptive models may include those that describe the functional or physical architecture of a system, or the three-dimensional geometric representation of a system.

Analytical Models

An analytical model describes mathematical relationships, such as differential equations that support quantifiable analysis about the system parameters. Analytical models can be further classified into dynamic and static models. Dynamic models describe the time-varying state of a system, whereas static models perform computations that do not represent the time-varying state of a system. A dynamic model may represent the performance of a system, such as the aircraft position, velocity, acceleration, and fuel consumption over time. A static model may represent the mass properties estimate or reliability prediction of a system or component.

Hybrid Descriptive and Analytical Models

A particular model may include descriptive and analytical aspects as described above, but models may favor one aspect or the other. The logical relationships of a descriptive model can also be analyzed, and inferences can be made to reason about the system. Nevertheless, logical analysis provides different insights than a quantitative analysis of system parameters.

Domain-Specific Models

Both descriptive and analytical models can be further classified according to the domain that they represent. The following classifications are partially derived from the presentation on *OWL, Ontologies and SysML Profiles: Knowledge Representation and Modeling* (Web Ontology Language (OWL) & Systems Modeling Language (SysML)) (Jenkins 2010):

- properties of the system, such as performance, reliability, mass properties, power, structural, or thermal models;
- design and technology implementations, such as electrical, mechanical, and software design models;
- subsystems and products, such as communications, fault management, or power distribution models; and
- system applications, such as information systems, automotive systems, aerospace systems, or medical device models.

The model classification, terminology and approach are often adapted to a particular application domain. For example, when modeling an organization or business, the behavioral model may be referred to as a workflow or process model, and the performance modeling may refer to the cost and schedule performance associated with the organization or business process.

A single model may include multiple domain categories from the above list. For example, a reliability, thermal, and/or power model may be defined for an electrical design of a communications subsystem for an aerospace system, such as an aircraft or satellite.

System Models

System models can be hybrid models that are both descriptive and analytical. They often span several modeling domains that must be integrated to ensure a consistent and cohesive system representation. As such, the system model must provide both general-purpose system constructs and domain-specific constructs that are shared across modeling domains. A system model may comprise multiple views to support planning, requirements, design, analysis, and verification.

Wayne Wymore is credited with one of the early efforts to formally define a system model using a mathematical framework in *A Mathematical Theory of Systems Engineering: The Elements* (Wymore 1967). Wymore established a rigorous mathematical framework for designing systems in a model-based context. A summary of his work can be found in A Survey of Model-Based Systems Engineering (MBSE) Methodologies.

Simulation versus Model

The term simulation, or more specifically computer simulation, refers to a method for implementing a model over time (DoD 1998). The computer simulation includes the analytical model which is represented in executable code, the input conditions and other input data, and the computing infrastructure. The computing infrastructure includes the computational engine needed to execute the model, as well as input and output devices. The great variety of approaches to computer simulation is apparent from the choices that the designer of a computer simulation must make, which include:

- stochastic or deterministic;
- steady-state or dynamic;
- continuous or discrete; and

- local or distributed.

Other classifications of a simulation may depend on the type of model that is being simulated. One example is an agent-based simulation that simulates the interaction among autonomous agents to predict complex emergent behavior (Barry 2009). There are many other types of models that could be used to further classify simulations. In general, simulations provide a means for analyzing complex dynamic behavior of systems, software, hardware, people, and physical phenomena.

Simulations are often integrated with the actual hardware, software, and operators of the system to evaluate how actual components and users of the system perform in a simulated environment. Within the United States defense community, it is common to refer to simulations as live, virtual, or constructive, where live simulation refers to live operators operating real systems, virtual simulation refers to live operators operating simulated systems, and constructive simulations refers to simulated operators operating with simulated systems. The virtual and constructive simulations may also include actual system hardware and software in the loop as well as stimulus from a real systems environment.

In addition to representing the system and its environment, the simulation must provide efficient computational methods for solving the equations. Simulations may be required to operate in real time, particularly if there is an operator in the loop. Other simulations may be required to operate much faster than real time and perform thousands of simulation runs to provide statistically valid simulation results. Several computational and other simulation methods are described in Simulation Modeling and Analysis (Law 2007).

Visualization

Computer simulation results and other analytical results often need to be processed so they can be presented to the users in a meaningful way. Visualization techniques and tools are used to display the results in various visual forms, such as a simple plot of the state of the system versus time to display a parametric relationship. Another example of this occurs when the input and output values from several simulation executions are displayed on a response surface showing the sensitivity of the output to the input. Additional statistical analysis of the results may be performed to provide probability distributions for selected parameter values. Animation is often used to provide a virtual representation of the system and its dynamic behavior. For example, animation can display an aircraft's three-dimensional position and orientation as a function of time, as well as project the aircraft's path on the surface of the Earth as represented by detailed terrain maps.

Integration of Models

Many different types of models may be developed as artifacts of a MBSE effort. Many other domain-specific models are created for component design and analysis. The different descriptive and analytical models must be integrated in order to fully realize the benefits of a model-based approach. The role of MBSE as the models integrate across multiple domains is a primary theme in the International Council on Systems Engineering (INCOSE) INCOSE Systems Engineering Vision 2020 (INCOSE 2007).

As an example, system models can be used to specify the components of the system. The descriptive model of the system architecture may be used to identify and partition the components of the system and define their interconnection or other relationships. Analytical models for performance, physical, and other quality characteristics, such as reliability, may be employed to determine the required values for specific component properties to satisfy the system requirements. An executable system model that represents the interaction of the system components may be used to validate that the component requirements can satisfy the system behavioral requirements. The descriptive, analytical, and executable system models each represent different facets of the same system.

The component designs must satisfy the component requirements that are specified by the system models. As a result, the component design and analysis models must have some level of integration to ensure that the design

model is traceable to the requirements model. The different design disciplines for electrical, mechanical, and software each create their own models representing different facets of the same system. It is evident that the different models must be sufficiently integrated to ensure a cohesive system solution.

To support the integration, the models must establish semantic interoperability to ensure that a construct in one model has the same meaning as a corresponding construct in another model. This information must also be exchanged between modeling tools.

One approach to semantic interoperability is to use model transformations between different models. Transformations are defined which establish correspondence between the concepts in one model and the concepts in another. In addition to establishing correspondence, the tools must have a means to exchange the model data and share the transformation information. There are multiple means for exchanging data between tools, including file exchange, use of application program interfaces (API), and a shared repository.

The use of modeling standards for modeling languages, model transformations, and data exchange is an important enabler of integration across modeling domains.

System Modeling Concepts

- Lead Author:
- Sanford Friedenthal
- Contributing Author:
- Dov Dori, Yaniv Mordecai

-

A system model represents aspects of a system and its environment. There are many different types of models, as there are a variety of purposes for which they are built. It is useful to have a common way to talk about the concepts underlying the many different types of models (e.g., many modeling techniques enable the understanding of system behavior, while others enable the understanding of system structure). This article highlights several concepts used for modeling systems.

Abstraction

Perhaps the most fundamental concept in systems modeling is abstraction, which concerns hiding unimportant details in order to focus on essential characteristics. Systems that are worth modeling have too many details for all of them to reasonably be modeled. Apart from the sheer size and structural complexity that a system may possess, a system may be behaviorally complex as well, with emergent properties, non-deterministic behavior, and other difficult-to-characterize properties. Consequently, models must focus on a few vital characteristics in order to be computationally and intellectually tractable. Modeling techniques address this complexity through various forms of abstraction. For example, a model may assume that structural characteristics of many individual components of a particular type are all the same, ignoring the small order differences between individuals in instances that occur in real life. In that case, those differences are assumed to be unimportant to modeling the structural integrity of those components. Of course, if that assumption is wrong, then the model could lead to false confidence in that structural integrity. There are two key concepts that are applied in regard to modeling different levels of abstraction, which are: view and viewpoint, and black-box and white-box modeling, which are described below. Although these two modeling methods are the most widely recognized, different modeling languages and tools employ other techniques as well.

View and Viewpoint

IEEE 1471, a standard for architecture modeling, defines "view" and "viewpoint" as follows:

- View - A representation of a whole system from the perspective of a related set of concerns.
- Viewpoint - A specification of the conventions necessary for constructing and using a view; a pattern or template from which to develop individual views by establishing the purposes and audience for a view and the techniques for its creation and analysis.

Even though IEEE 1471 is focused on architecture models, the concepts of view and viewpoint are general and could apply to models for other purposes as well (IEEE 2000). The viewpoint addresses the concerns of the stakeholders and provides the necessary conventions for constructing a view to address those concerns; therefore, the view represents aspects of the system that address the concerns of the stakeholder. Models can be created to represent the different views of the system. A systems model should be able to represent multiple views of the system to address a range of stakeholder concerns. Standard views may include requirements, functional, structural, and parametric views, as well as a multitude of discipline-specific views to address system reliability, safety, security, and other quality characteristics.

Black-Box and White-Box Models

A very common abstraction technique is to model the system as a black-box, which only exposes the features of the system that are visible from an external observer and hides the internal details of the design. This includes externally visible behavior and other physical characteristics, such as the system's mass or weight. A white-box model of a system, on the other hand, shows the internal structure and displays the behavior of the system. Black-box and white-box modeling can be applied to the next level of design decomposition in order to create a black-box and white-box model of each system component.

Conceptual Model

A conceptual model is the set of concepts within a system and the relationships among those concepts (e.g., view and viewpoint). A system conceptual model describes, using one diagram type (such as in Object-Process Methodology (OPM)) or several diagram types (such as in Systems Modeling Language (SysML)), the various aspects of the system. The conceptual model might include its requirements, behavior, structure, and properties. In addition, a system conceptual model is accompanied by a set of definitions for each concept. Sometimes, system concept models are defined using an entity relationship diagram, an object-process diagram (OPD), or a Unified Modeling Language (UML) class diagram.

A preliminary conceptual (or concept) model for systems engineering (Systems Engineering Concept Model) was developed in support of the integration efforts directed toward the development of the Object Management Group (OMG) SysML and the International Organization for Standardization (ISO) AP233 *Data Exchange Standard for Systems Engineering* (ISO 2010). The concept model was originally captured in an informal manner; however, the model and associated concepts were rigorously reviewed by a broad representation of the systems engineering community, including members from the International Council on Systems Engineering (INCOSE), AP233, and SysML development teams.

A fragment from the top level systems engineering concept model is included in Figure 1. This model provides concepts for requirements, behavior, structure and properties of the system, as well as other concepts common to systems engineering and project management, such as the stakeholder. The concept model is augmented by a well-defined glossary of terms called the semantic dictionary. The concept model and the semantic dictionary contributed greatly to the requirements for the OMG Systems Modeling Language written in the UML for Systems Engineering Request for Proposal.

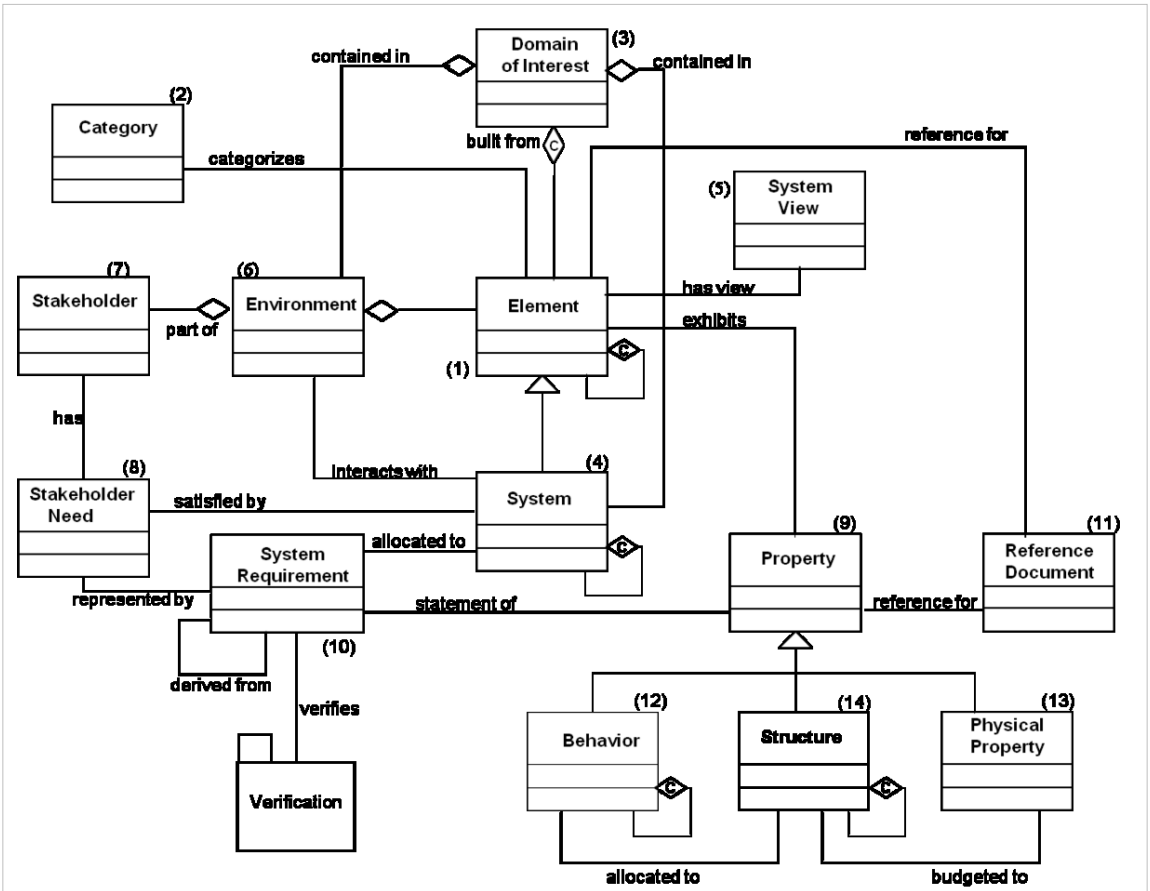

Figure 1. Fragment of the Object Management Group System Concept Model (Oliver 2003, Slide 3). Permission granted by David Oliver on behalf of INCOSE MDSD Working Group. All other rights are reserved by the copyright owner.

A concept model is sometimes referred to as a meta-model, domain meta-model, or schema, and can be used to specify the abstract syntax of a modeling language (refer to the Model Driven Architecture (MDA®) Foundation Model (OMG 2010)). Several other systems engineering concept models have been developed but not standardized. Future standardization efforts should establish a standard systems engineering concept model. The model can then evolve over time as the systems engineering community continues to formalize and advance the practice of systems engineering.

Integrating Supporting Aspects into System Models

- Lead Author:
- Sanford Friedenthal
- Contributing Authors:
- Dov Dori and Yaniv Mordecai

-

This article discusses the integrated modeling of systems and supporting aspects using Model-Based Systems Engineering methodologies and frameworks. Supporting aspects of systems engineering include:

- Engineering Management
- Project Management
- Requirements Engineering and Management
- Risk Modeling, Analysis, and Management
- Quality Assurance, Testing, Verification, and Validation
- System Integration and Employment
- Analysis of "-ilities" (e.g., Reliability, Availability, Maintainability, Safety, And Security (RAMSS), Manufacturability, Extensibility, Robustness, Resilience, Flexibility, and Evolvability)

These aspects can pertain to physical facets, as well as to functional, structural, behavioral, social, and environmental facets of the core system model. The article focuses on three main aspects:

1. Project and Engineering Management
2. Risk Modeling, Analysis, and Management
3. Requirements Definition and Management

Background

The model-based approach to systems engineering considers the system model as much more than a plain description of the system; the model is the central common basis for capturing, representing, and integrating the various system aspects listed above. The model is essential to the design and understanding of the system as well as to managing its life cycle and evolution. Modeling languages constitute the basis for standardized, formal descriptions of systems, just like natural languages form the basis for human communication.

As systems progressively become more complex and multidisciplinary, the conceptual modeling of systems needs to evolve and will become more critical for understanding complex design (Dori 2002). In addition to facilitating communication among clients, designers, and developers, conceptual modeling languages also assist in clearly describing and documenting various domains, systems, and problems, and define requirements and constraints for the design and development phases (Wand and Weber 2002). The importance of model-based analysis is demonstrated by the variety of conceptual modeling methodologies and frameworks, although *de facto* standards are slow to emerge. While certain disciplines of engineering design, such as structural analysis or circuit design, have established modeling semantics and notation, the conceptual modeling of complex systems and processes has not yet converged on a unified, consolidated modeling framework (Estefan 2007). The challenge is not only to integrate multiple aspects and support the various phases of the system's life cycle, but also to capture the multidisciplinary nature of the system, which has led to the creation of various frameworks. Nevertheless, the information systems analysis paradigm is currently the most widely used, perhaps due to the need to integrate complex systems via information-intensive applications and interactions.

Integrated Modeling of Systems and Projects

This section discusses the integrated modeling of systems and projects and of the project-system relationship (often called Project-Product Integration). The fields of project management and systems engineering have been advancing hand-in-hand for the last two decades, due to the understanding that successful projects create successful systems. Many of the main systems engineering resources pay considerable attention to project management and consider it to be a critical process and enabler of systems engineering (INCOSE 2012; NASA 2007; Sage and Rouse 2011). The integration of system-related aspects and concepts into project plans is more common than the integration of project-related aspects and concepts into system models. Because the project is a means to an end, it is the process that is expected to deliver the system. Indeed, project activities are often named after or in accord with the deliverables that they are aimed at facilitating (e.g., "console design," "software development," "hardware acquisition," or "vehicle assembly"). Each is a function name, consisting of an object (noun), or the system to be attained, and a process (verb), being the project or part of the project aimed at attaining the end system.

The specific process associated with each of these examples refers to different stages or phases of the project and to different maturity levels of the system or sub-system to which it applies. Moreover, the mere inclusion of system and part names in activity names does not truly associate system model artifacts with these activities. Overall, it is not truly possible to derive the set of activities associated with a particular part or functionality of the system that will be delivered by the project. Project-Product integration is not straightforward, as project models and system models are traditionally disparate and hardly interface. A model-based approach to project-system integration follows a system-centric paradigm and focuses on incorporating project-related aspects and concepts into the core system model, as opposed to the project-centric approach described in the previous paragraph. Such aspects and concepts include schedule, budget and resources, deliverables, work-packages, constraints and previous relations. The integrated system-project model should provide useful information on the mutual effects of project activities and system components and capabilities. Some examples of integrated system-project modeling include the following:

- The set of project activities associated with a particular system component, feature, or capability.
- The set of resources required for performing a task of designing or developing a particular component of the system.

- The team or subcontractor responsible for delivering each system component.
- The preexisting dependencies between activities of system components deployment.
- The cost associated with each system component, feature, or capability.
- The parts of the system negotiated for each delivery, deployment, build, release, or version.

The Work Breakdown Structure (WBS) is designed to support the division of the project scope (work content) amongst the individuals and organizations participating in the project (Golany and Shtub 2001). The WBS is traditionally organization or activity-oriented; however, one of its main cornerstones focuses on the deliverable, which corresponds to the system, sub-system, component, or a capability or feature of one or more of these. A deliverable-oriented WBS, in which the high-level elements correspond to primary sub-systems, is advocated, as it is likely to allow the WBS to be more product-oriented (Rad 1999). An integrated approach to project planning and system modeling (Sharon and Dori 2009) merges the system model with the project's WBS using Object-Process Methodology (OPM) (Dori 2002). The unified OPM model captures both the project activities and the system components and functionalities.

The Design Structure Matrix (DSM) is a common method for enhancing and analyzing the design of products and systems. DSMs can be component-based, task-based, parameter-based, or team-based (Browning 2001). A DSM for an OPM-based project-product model derives a hybrid DSM of project activities and system building blocks from the unified OPM model, accounting for dependencies between project activities and system components, as well as replacing the two monolithic and separate component-based and task-based DSM views (Sharon, De-Weck, and Dori 2012). The underlying OPM model assures model consistency and traceability. The integrated project-product OPM model includes both a diagram and an equivalent auto-generated textual description. The DSM derived from this model visualizes a dependency loop comprising both system components and project activities.

Another model-based approach (Demoly et al. 2010) employs System Modeling Language (SysML) in order to create various views that meet the needs of various system stakeholders, such as the project/process manager. The approach includes both product-oriented and process-oriented views.

Integrated Modeling of Systems and Requirements

Requirements are statements that describe operational, functional, or design-related aspects of a system. Requirements definition and management is an important SE process, as it both initiates and facilitates the entire SE effort by defining the expected functions and performance of the engineered system. Several challenges associated with requirements include:

- Defining the requirements in a structured, controlled manner.
- Tracing these requirements to system components, aspects, and decisions.
- Testing and verifying compliance of the system with these requirements.

The extension of conceptual system models to include requirements has several significant benefits:

1. Requirements provide the rationale for the system's architecture and design by making and justifying architectural and design decisions based on specific requirements.
2. Modeling the internal logic and the hierarchy and dependency relations among requirements enables identification and elimination of redundant and contradictory requirements.
3. Teams and persons responsible for delivering various system components can often take responsibility for satisfying specific requirements. While the advantages of having good requirements engineering is clear, it is often a challenge to directly trace requirements to specific system artifacts, especially when the requirements are defined in a holistic, solution-independent manner.

There are several methods to incorporate requirements into system models, including SysML Requirements Engineering and Object-Process Methodology (OPM)-based Requirements Engineering and Authoring.

SysML-Based Requirements Engineering

The SysML requirements diagram makes it possible to capture the requirements and the relations among them in a visual manner, which is more intuitive than the textual manner in which requirements are traditionally edited and managed. The diagram was added to the basic set of UML diagrams that formed the basis for SysML (Friedenthal, Moore, and Steiner 2006), and is not a native UML diagram. Tracing requirements to the system blocks and artifacts satisfying them can be captured in the SysML Block Definition Diagram, which is primarily designated to capture the relations among types of system elements and components. The < > link between the block and the requirement captures the trace.

OPM-Based Requirements Engineering

Object-Process Methodology (OPM) is a methodology and language for conceptual modeling of complex systems and processes with a bimodal textual and graphical representation (Dori 2002). OPM's textual representation is coordinated with the graphical representation; additionally, each visual model construct in the Object-Process Diagram (OPD) is described by a formal structured textual statement in Object-Process Language (OPL), which is a subset of natural English. OPM facilitates model-based requirements engineering, authoring, and specification, in three possible modes:

1. OPM can be used to generate conceptual models which initially focus on the requirements level—the problem domain, rather than the design level or the solution domain, which facilitates automated model-based requirements generation (Blekhman and Dori 2011). The requirements model is solution-neutral, and it can be the basis for one or more architectural solutions for achieving the functions specified in the requirements.
2. OPM can be utilized in order to generate requirement-oriented OPDs in a manner similar to how the SysML Requirements Diagram enables an engineer to capture the requirements specification as the skeleton for the system model. User-defined tagged structural relations, such as "is realized by" or is allocated to," provide for associating requirements with system model functions (objects and processes that transform them). This approach is similar to the SysML requirements diagram; however, instead of using a unique notation in a separate diagram type, the requirements are seamlessly incorporated into the single system model.
3. OPM can be used for the purpose of generating visual system models from formally specified requirements by tracing the textually authored requirements to system model inserts and artifacts (Dori et al. 2004).

Integrating Risk into System Models

Risk is an expression and a measure of the negative or adverse impact of uncertainty. Risk exists whenever uncertainty can lead to several results, of which some may be negative (adverse) and some positive. A system faces risks from other systems or from the environment, and it can also pose risks to other systems or to the environment. Systems are characterized by such attributes, such as: goals, objectives, inputs, outputs, variables, parameters, processes, events, states, subsystems, interfaces, mechanisms, and methods. System vulnerability is the system's total potential to be harmed or negatively affected in any one of these attributes. Analogously, system harmfulness is the system's total potential to harm others or to generate negative effects, which can be manifested in one or more of these attributes (Haimes 2009). Model-based risk analysis (MBRA) enables structured analysis and risk-related process control. Several model-based risk analysis approaches are available in the literature. MBRA is presently more common in the information technology and information security domains than in the systems engineering domain; however, some of the methods are generally applicable to complex systems as well. The ISO-IEC-IEEE collaborative software development and operation lifecycle standard (ISO and IEC 2004) proposes a concurrent approach to IT Risk Management. This approach consists of six main activities:

- Plan and Implement Risk Management
- Manage the Project Risk Profile
- Perform Risk Analysis

- Perform Risk Monitoring
- Perform Risk Treatment
- Evaluate the Risk Management Process

These activities are executed concurrently, affect and provide feedback to each other, and interact with other software life cycle processes, such as the technical management and the design processes (ISO and IEC 2004).

The CORAS approach (Fredriksen et al. 2002; den Braber et al. 2006; Lund, Solhaug, and Stølen 2011) is a UML-derivative for IT security risk modeling and assessment. This framework consists mostly of the UML use case (UC) diagram, extended for misuse cases. Additional notation was added to the UC notation in order to capture risk sources, effects, and results (e.g., the "bad actor" icon, moneybag for asset-in-risk). A misuse diagram can include, for example, the risk of loss of legal protection of proprietary know-how due to information theft and distribution by an unfaithful employee. The treatment for the risk source of insufficient security policy, which contributes to the above risk, is illustrated in a separate treatment diagram.

A quantitative risk assessment method for component-based systems (Grunske and Joyce 2008) supports component vulnerability analysis and specification using modular attack trees. In addition, it provides attacker profiling, which enables supporting econometric approaches to risk response. The methodology utilizes SysML as its underpinning language, especially the SysML block definition diagram and parametric diagram, in order to capture parametric relations and constraints as a means to defining risk profiles.

System-Theoretic Accident Model and Processes (STAMP) is a method for system and component design for safety (Leveson 2011). STAMP reformulates the safety problem as a control problem as opposed to a reliability problem. STAMP is optimized for safety-oriented systems engineering and design and for hazard avoidance and mitigation, specifically in complex socio-technical systems. A model-based adaptation of STAMP was also proposed (Leveson 2004) and was implemented in various safety-critical and mission-critical systems, including aircraft collision avoidance systems (CAS) (Leveson 2004) and ballistic missile defense systems (Pereira, Lee, and Howard 2006). Risk-Oriented Systems Engineering (ROSE) (Mordecai and Dori 2013) is a method based on Object-Process Methodology (OPM) for integrating risk into system models. Being system-centric, ROSE is responsible for capturing risk layers and aspects on top of and in sync with the core system model, while improving and immunizing it against captured risks, as well as for generating system robustness and resilience by design in response to various risk-posing scenarios. The risk handling meta-model includes risk mitigation during the design phase and risk response during the operational phase.

Modeling Standards

- Lead Author:
- Sanford Friedenthal
- Contributing Authors:
- Dov Dori and Yaniv Mordecai

-

Different types of models are needed to support the analysis, specification, design, and verification of systems. The evolution of modeling standards enables the broad adoption of Model-Based Systems Engineering (MBSE).

Motivation for Modeling Standards

Modeling standards play an important role in defining agreed-upon system modeling concepts that can be represented for a particular domain of interest and enable the integration of different types of models across domains of interest. Modeling standards are extremely important to support MBSE, which aims to integrate various system aspects across various disciplines, products, and technologies.

Standards for system modeling languages can enable cross-discipline, cross-project, and cross-organization communication. This communication offers the potential to reduce the training requirements for practitioners who only need to learn about a particular system and enables the reuse of system artifacts. Standard modeling languages also provide a common foundation for advancing the practice of systems engineering, as do other systems engineering standards.

Types of Modeling Standards

Many different standards apply to systems modeling. Modeling standards include standards for modeling languages, data exchange between models, and the transformation of one model to another to achieve semantic interoperability. Each type of model can be used to represent different aspects of a system, such as representing the set of system components and their interconnections and interfaces, or to represent a system to support performance analysis or reliability analysis.

The following is a partial list of representative modeling standards, which also includes the common acronym, when applicable, and a reference as to where additional information can be found on the topic.

Modeling Languages for Systems

Descriptive Models - These standards apply to general descriptive modeling of systems:

- Functional Flow Block Diagram (FFBD) (Oliver, Kelliher, and Keegan 1997)
- Integration Definition for Functional Modeling (IDEF0) (NIST 1993)
- Object-Process Methodology (OPM) [[1]] (Dori 2002; ISO/PAS 19450:2015)
- Systems Modeling Language (SysML)(OMG 2010a)
- Unified Profile for United States Department of Defense Architecture Framework (DoDAF) and United Kingdom Ministry of Defence Architecture Framework (MODAF) (OMG 2011e)
- Web ontology language (OWL) (W3C 2004b)

Analytical Models and Simulations - These standards apply to analytical models and simulations:

- Distributed Interactive Simulation (DIS) (IEEE 1998)
- High-Level Architecture (HLA) (IEEE 2010)
- Modelica (Modelica Association 2010)
- Semantics of a Foundational Subset for Executable Unified Modeling Language (UML) Models (FUML) (OMG 2011d)

Data Exchange Standards

These standards enable the exchange of information between models:

- Application Protocol for Systems Engineering Data Exchange (ISO 10303-233) (AP-233) (ISO 2005)
- Requirements Interchange Format (ReqIF) (OMG 2011c)
- Extensible Mark-Up Language - (XML) Metadata Interchange (XMI) (OMG 2003a)
- Resource Description Framework (RDF) (W3C 2004a)

Model Transformations

These standards apply to transforming one model to another to support semantic interoperability:

- Query View Transformations (QVT) (OMG 2011b)
- Systems Modeling Language (SysML)-Modelica Transformation (OMG 2010c)
- OPM-to-SysML Transformation (Grobshtein and Dori 2011)

General Modeling Standards

These standards provide general frameworks for modeling:

- Model-driven architecture (MDA®) (OMG 2003b)
- IEEE 1471-2000 - Recommended Practice for Architectural Description of Software-Intensive Systems (ANSI/IEEE 2000) (ISO/IEC 2007)

Other Domain-Specific Modeling Standards

Software Design Models

These standards apply to modeling application software and/or embedded software design:

- Architecture Analysis and Design Language (AADL) (SAE 2009)
- Modeling and Analysis for Real-Time and Embedded Systems (MARTE) (OMG 2009)
- Unified Modeling Language (UML) (OMG 2010b)

Hardware Design Models

These standards apply to modeling hardware design:

- Very-High-Speed Integrated Circuit (VHSIC) Hardware Description Language (VHDL) (IEEE 2008)

Business Process Models

These standards apply to modeling business processes:

- Business Process Modeling Notation (BPMN) (OMG 2011a)

This knowledge area (KA) provides a guide for applying the systems approach as a means of identifying and understanding complex problems and opportunities, synthesizing possible alternatives, analyzing and selecting the best alternative, implementing and approving a solution, as well as deploying, using and sustaining engineered system solutions. The active participation of stakeholders during all the activities of the systems approach is the key to the success of the systems approach.

In an engineered system context, a systems approach is a holistic approach that spans the entire life of the system; however, it is usually applied in the development and operational/support life cycle stages. This knowledge area defines a systems approach using a common language and intellectual foundation to ensure that practical systems concepts, principles, patterns and tools are accessible to perform systems engineering (SE), as is discussed in the introduction to Part 2: Foundations of Systems Engineering.

Topics

Each part of the Guide to the SE Body of Knowledge (SEBoK) is divided into KAs, which are groupings of information with a related theme. The KAs, in turn, are divided into topics. This KA contains the following topics:

- Overview of the Systems Approach
- Engineered System Context
- Identifying and Understanding Problems and Opportunities
- Synthesizing Possible Solutions
- Analysis and Selection between Alternative Solutions
- Implementing and Proving a Solution
- Deploying, Using, and Sustaining Systems to Solve Problems
- Applying the Systems Approach

Systems Approach

This KA describes a high-level framework of activities and principles synthesized from the elements of the systems approach, as described earlier in Part 2 of the SEBoK, and is mapped to the articles Concepts of Systems Thinking, Principles of Systems Thinking, and Patterns of Systems Thinking. The concept map in Figure 1 describes how the knowledge is arranged in this KA and the linkage to the KA in Part 3.

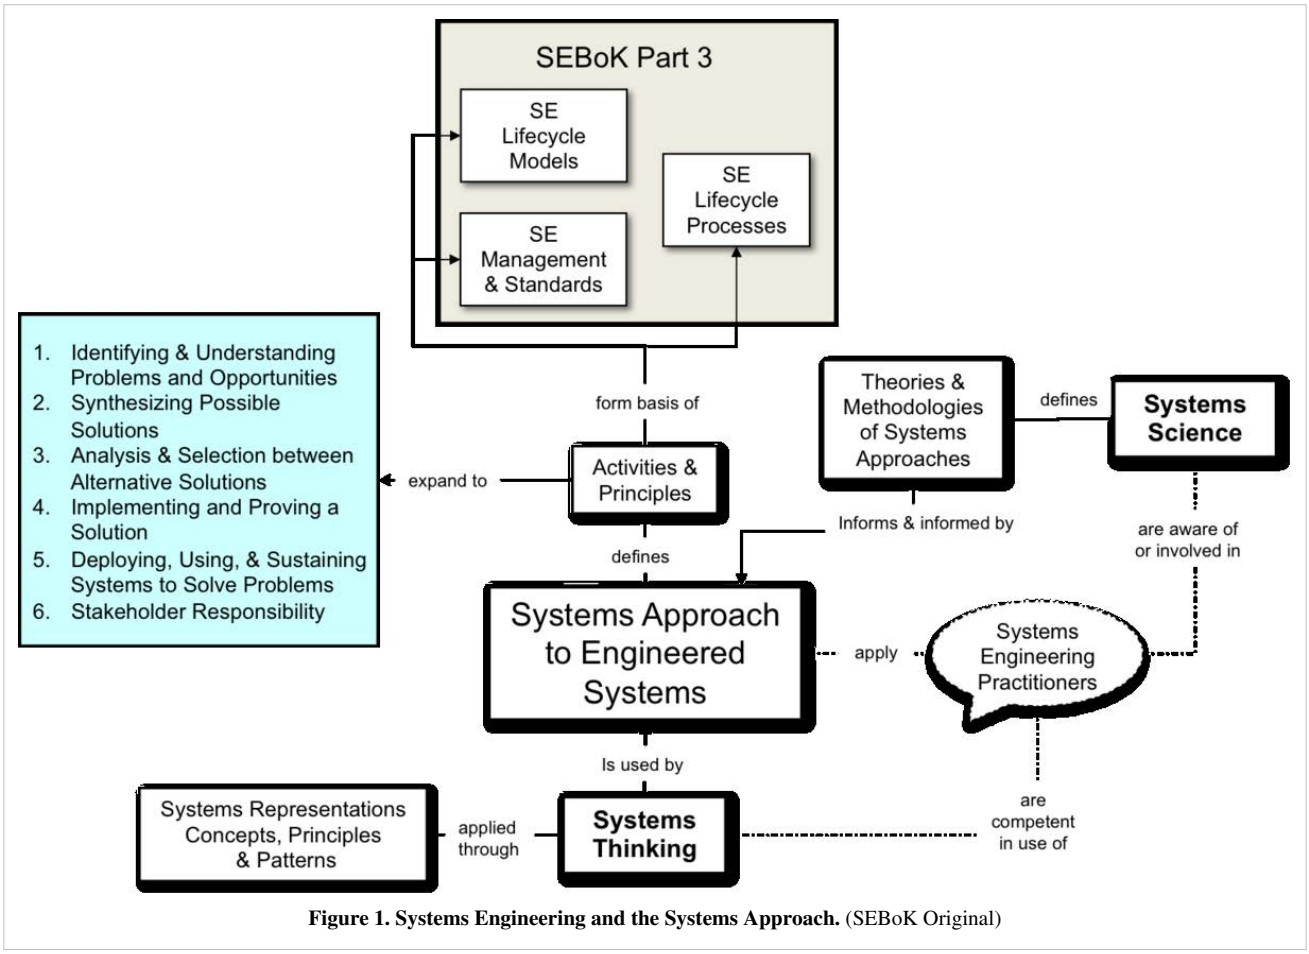

Figure 1. Systems Engineering and the Systems Approach. (SEBoK Original)

According to Jackson et al. (2010, 41-43), the systems approach to engineered systems is a problem-solving paradigm. It is a comprehensive problem identification and resolution approach based upon the principles, concepts, and tools of systems thinking and systems science, along with the concepts inherent in engineering problem-solving. It incorporates a holistic systems view that covers the larger context of the system, including engineering and operational environments, stakeholders, and the entire life cycle.

Successful systems practice should not only apply systems thinking to the system being created but should also utilize systems thinking in consideration of the way in which work is planned and conducted. See Part 5: Enabling Systems Engineering for further discussions on how individuals, teams, businesses and enterprises may be enabled to perform systems engineering.

Overview of the Systems Approach

Lead Author: *Rick Adcock*, ***Contributing Authors:*** *Janet Singer, Duane Hybertson, Hillary Sillitto, Bud Lawson, Brian Wells, James Martin*

This knowledge area (KA) considers how a systems approach relates to engineered systems and to systems engineering (SE). The article Applying the Systems Approach considers the dynamic aspects of how the approach is used and how this relates to elements of SE.

PROJECT PERFORMANCE INTERNATIONAL

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

Systems Approach and Systems Engineering

The term systems approach is used by systems science authors to describe a systems *"thinking"* approach, as it pertains to issues outside of the boundary of the immediate system-of-interest (Churchman 1979). This systems approach is essential when reductionist assumptions (the notion that the whole system has properties derived directly from the properties of their components) no longer apply to the system-of-interest (SoI) and when emergence and complexity at multiple levels of a system context necessitate a holistic approach.

The systems approach for engineered systems is designed to examine the *"whole system, whole lifecycle, and whole stakeholder community"* as well as to ensure that the purpose of the system (or systemic intervention) is achieved sustainably without causing any negative unintended consequences. This prevents the engineer from *"transferring the burden"* (in systems thinking terms) to some other part of the environment that unable to sustain that burden (Senge 2006). This also deters issues involving *sub-optimization* that could occur when whole systems are not kept in mind in achieving the purpose of the system (Sillitto 2012).

The systems approach (derived from systems thinking) and systems engineering (SE) have developed and matured, for the most part, independently; therefore, the systems science and the systems engineering communities differ in their views as to what extent SE is based on a systems approach and how well SE uses the concepts, principles, patterns and representations of systems thinking. These two views are discussed in the following sections.

Systems Science View

As discussed in the Systems Science article, some parts of the systems movement have been developed as a reaction to the perceived limitations of systems engineering (Checkland 1999).

According to Ryan (2008):

> ***Systems engineering has a history quite separate to the systems movement.*** *Its closest historical link comes from the application of systems analysis techniques to parts of the systems engineering process . . . The recent popularity of the SoS buzzword in the systems engineering literature has prompted* ***the expansion of systems engineering techniques to include methods that can cope with evolving networks of semi-autonomous systems. This has led many systems engineers to read more widely across the systems literature, and is providing a re-conceptualization of systems engineering as part of the systems movement, despite its historical independence. This is reflected in the latest INCOSE hand-book [INCOSE 2011, page 52], which states "the systems engineering perspective is based on systems thinking", which "recognizes circular causation, where a variable is both the cause and the effect of another and recognizes the primacy of interrelationships and non-linear and organic***

***thinking—a way of thinking where the primacy of the whole is acknowledged.* (emphases added)**

Thus, for many in the systems science community, systems thinking is *not* naturally embedded in either SE definitions or practice.

Systems Engineering View

Many SE authors see a clear link between SE and systems thinking. For example, Hitchins (Hitchins 2007) describes generic models for the application of systems thinking to engineered system contexts. He suggests that these could form the foundation for descriptions and standards for the practices of SE. Hitchins also proposes a set of *guiding principles which have been the foundations of SE, apparently since its inception* (Hitchins 2009):

- **SE Principle A: The Systems Approach** - *"SE is applied to a system-of-interest (SoI) in a wider systems context"*
- **SE Principle B: Synthesis** - *"SE must bring together a collection of parts to create whole system solutions"*
- **SE Principle C: Holism** - *"Always consider the consequences on the wider system when making decisions about the system elements"*
- **SE Principle D: Organismic Analogy** - *"Always consider systems as having dynamic "living" behavior in their environment"*
- **SE Principle E: Adaptive Optimizing** - *"Solve problems progressively over time"*
- **SE Principle F: Progressive Entropy Reduction** - *"Continue to make systems work over time, through maintenance, sustainment and, upgrade activities."*
- **SE Principle G: Adaptive Satisfying** - *"A system will succeed only if it makes winners of its success-critical stakeholders, so the lifecycle of a system must be driven by how well its outputs contribute to stakeholder purpose"*

Hitchins considers principles A-D as pillars of SE that identify key aspects of systems thinking which should underpin the practice of SE. Principles E-G consider the dynamics of SE life cycle thinking, the *why*, *when* and *how often* of SE.

The following sections consider the systems approach to engineered systems against four themes.

1. Whole System

The system coupling diagram (Figure 1), describes the scope of a systems approach to engineered systems (Lawson 2010).

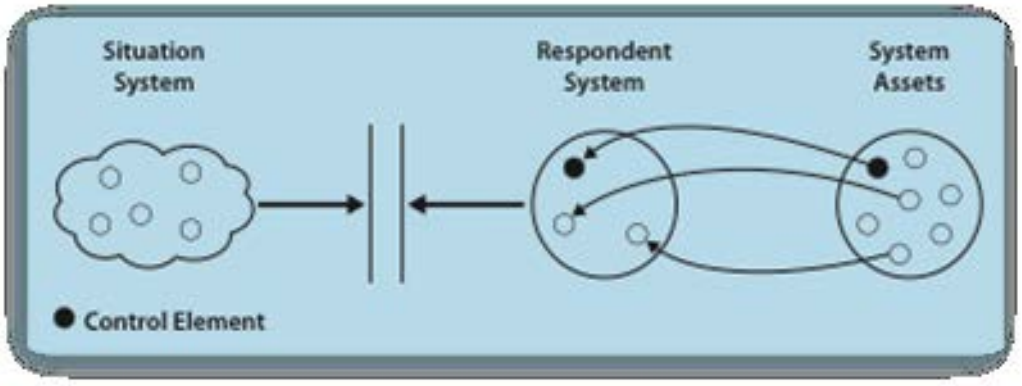

Figure 1. System Coupling Diagram (Lawson 2010). Reprinted with permission of Harold "Bud" Lawson. All other rights are reserved by the copyright owner.

- The **situation system** is the problem or opportunity either unplanned or planned. The situation may be natural, man-made, a combination of both, or a postulated situation used as a basis for deeper understanding and training (e.g. business games or military exercises).

- The **respondent system** is the system created to respond to the situation. The parallel bars indicate that this system interacts with the situation and transforms it to a new situation. Respondent systems have several names:, project, program, mission, task force, or in a scientific context, experiment.
- **System assets** are the sustained assets of one or more enterprises to be used in response to situations. System assets must be adequately managed throughout the life of a system to ensure that they perform their function when instantiated in a respondent system. Examples include: value-added products or services, facilities, instruments and tools, and abstract systems, such as theories, knowledge, processes and methods.

Martin (Martin 2004) describes seven types of system, or *"the seven samurai of systems engineering,"*, all of which, system developers need to understand to develop successful systems:

- the context system
- the intervention system
- the realization system
- the deployed system
- collaborating systems
- the sustainment system
- competing systems

Martin contends that all seven systems must be explicitly acknowledged and understood when engineering a solution for a complex adaptive situation.

These views, and others, describe one aspect of the systems approach when applied to engineered systems; in addition, it is applicable to understanding a problem, it organizes the resolution of that problem, and creates and integrates any relevant assets and capabilities to enable that solution.

2. Whole Lifecycle

Ring (Ring 1998) provides a powerful framework for the continuing management and periodic upgrade of long-life and *"immortal"* systems. It also accurately represents the *"continuous"* or very rapid product launch and refreshment cycle driven by market feedback and constant innovation that is seen in most product and service system consumer markets.

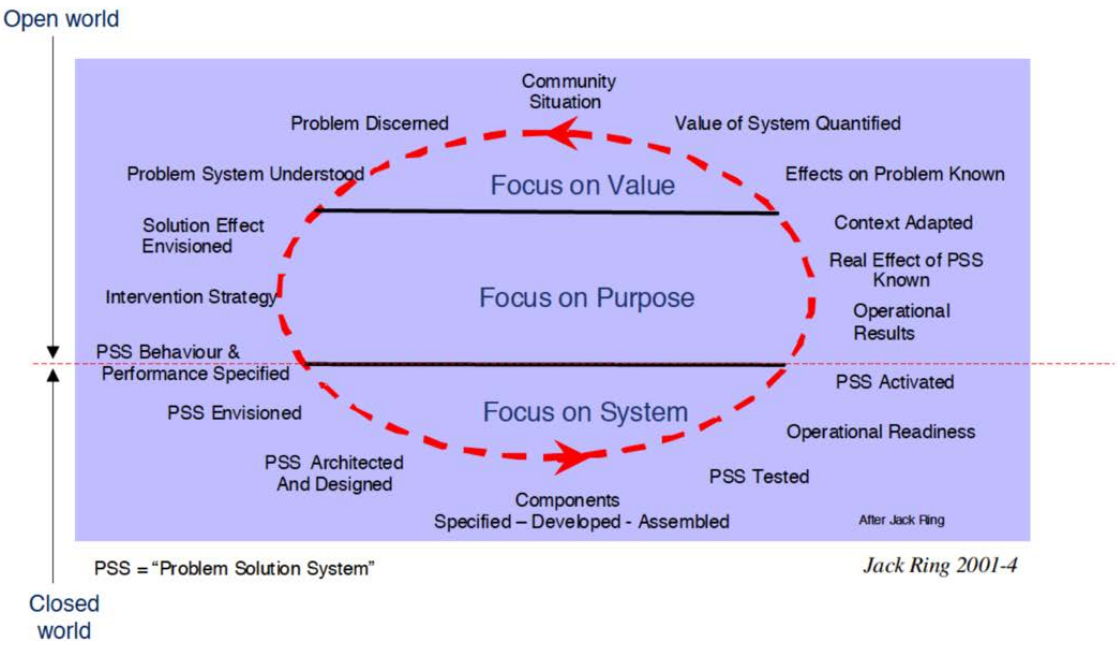

Figure 2. Ellipse Graphic (Ring 1998). © 1998 IEEE. Reprinted, with permission, from Jack Ring, Engineering Value-Seeking Systems, IEEE-SMC. Conference Proceedings. All other rights are reserved by the copyright owner.

Enterprise systems engineering may be considered in multiple concurrent instances of this model for different sub-sets of enterprise assets and services, in order to maintain a capability to pursue enterprise goals in a complex and dynamic external environment.

The dynamic nature of this cycle and its relationship to Life Cycle thinking is discussed in the article Applying the Systems Approach.

3. Whole Problem

The article Identifying and Understanding Problems and Opportunities considers the nature of problem situations. It discusses the relationship between hard system and soft system views of problems and how they relate to engineered systems. Engineered systems are designed to operate with and add value to a containing social and/or ecological system. The scope of problems is captured by frameworks, such as Political, Economic, Social, Technological, Legal and Environmental (PESTLE) (Gillespie 2007) or Social, Technical, Economic, Environmental, Political, Legal, Ethical and Demographic (STEEPLED).

The idea of a wicked problem (Rittel and Webber 1973) is also discussed. These problems cannot be quantified and solved in a traditional engineering sense.

Sillitto (Sillitto 2010) describes a lifecycle model in which the decision as to what parts of problems can be *"solved"* and what parts must be *"managed"* is the first key decision and emphasizes the need for a solution approach that provides flexibility in the solution to match the level of uncertainty and change in the problem and stakeholder expectations. It is now normal to view a problem as one that *"changes over time"* and to promote the belief that value is determined by the perceptions of key stakeholders.

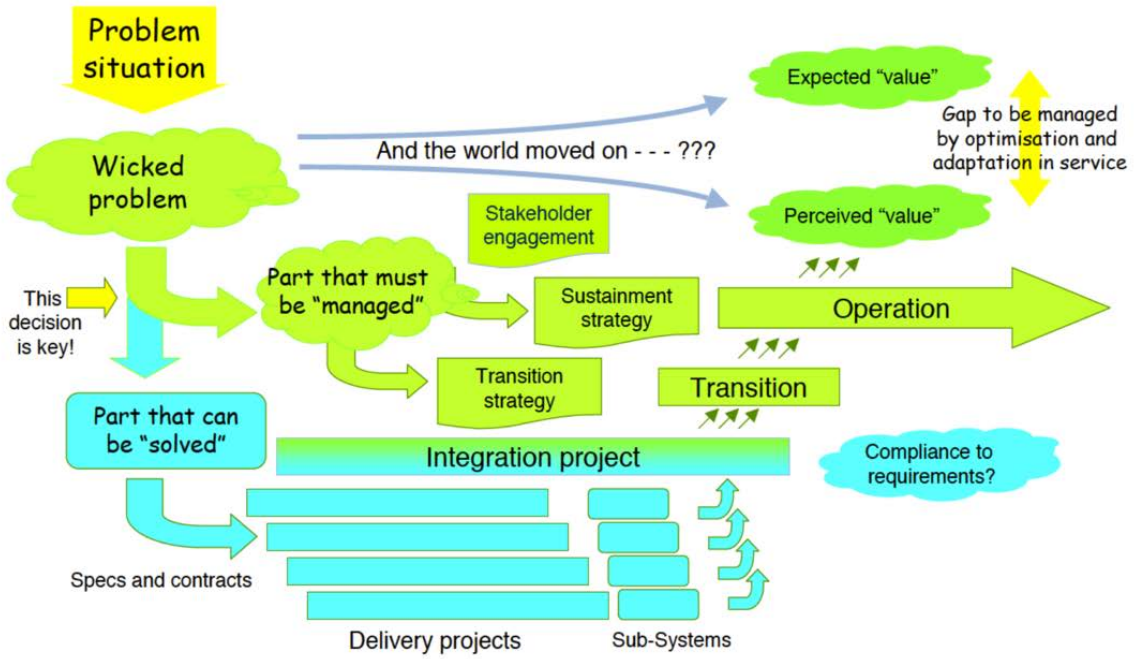

Figure 3. Engineered vs Managed Problems (Sillitto 2010). Reproduced with permission of Hillary Sillitto. All other rights are reserved by the copyright owner.

Thus, a systems approach can be useful when addressing all levels of a problematic situation, from individual technologies to the complex socio-technical issues that come about in the area of engineered systems development.

4. Multi-Disciplinary

As discussed by Sillitto (Sillitto 2012), the methods and thinking applied by many practicing systems engineers have become optimized to the domains of practice. While systems thinking concepts, patterns and methods are used widely, they are not endemic in SE practice. As a result, SE practitioners find it difficult to share systems ideas with others involved in a systems approach. Part 4: Applications of Systems Engineering describes traditional (product based) SE (Lawson 2010) and examines this against the SE approaches that are applicable to service, enterprise, and system of systems capability. These approaches require more use of problem exploration, a broader solution context, and a purpose driven life cycle thinking.

SE and Systems Approach

From the above discussions, there are three ways in which SE could make use of a systems approach:

- in its overall problem- solving approach
- in the scope of problem and solution system contexts considered
- in the embedding of systems thinking and systems thinking tools and in all aspects of the conduct of that approach

The current SE standards and guides, as described in Part 3: Systems Engineering and Management, encapsulate many of the elements of a systems approach. However, they tend to focus primarily on the development of system solutions while the wider purpose-driven thinking of a full systems approach (Ring 1998) and the wider consideration of all relevant systems (Martin 2004) are embedded in the acquisition and operational practices of their application domains.

The inclusion of systems thinking in SE competency frameworks (INCOSE 2010) represents a general move toward a desire for more use of systems thinking in SE practice. There is a wide stakeholder desire to acquire the benefits of a systems approach through the application of SE, particularly in areas where current SE approaches are inadequate or irrelevant. Hence, there is a need for a better articulation of the *systems approach* and how to apply it to non-traditional problems.

Synthesis for SEBOK

The systems approach presented in the SEBoK uses the following activities:

- identify and understand the relationships between the potential problems and opportunities in a real worldreal-world situation
- gain a thorough understanding of the problem and describe a selected problem or opportunity in the context of its wider system and its environment
- synthesize viable system solutions to a selected problem or opportunity situation
- analyze and choose between alternative solutions for a given time/cost/quality version of the problem.
- provide evidence that a solution has been correctly implemented and integrated
- deploy, sustain, and apply a solution to help solve the problem (or exploit the opportunity)

All of the above are considered within a life cycle (glossary) framework which may need concurrent, recursive (glossary) and iterative applications of some or all of the systems approach.

When the systems approach is executed in the real world of an engineered system (glossary), a number of engineering and management disciplines emerge, including SE. Part 3: Systems Engineering and Management and Part 4: Applications of Systems Engineering contain a detailed guide to SE with references to the principles of the systems approach, where they are relevant. Part 5: Enabling Systems Engineering provides a guide to the relationships between SE and the organizations and Part 6: Related Disciplines also offers a guide to the relationship between SE and other disciplines.

More detailed discussion of how the systems approach relates to these engineering and management disciplines is included in the article Applying the Systems Approach within this KA.

Engineered System Context

- Lead Author:
- Rick Adcock
- Contributing Authors:
- Brian Wells, Scott Jackson, and James Martin

-

This article is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the further expansion of the ideas of an engineered system and engineered system context that were introduced in the Systems Fundamentals KA.

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

The single most important principle of the systems approach is that it is applied to an engineered system context and not just to a single system (INCOSE 2012). The systems approach includes models and activities useful for the understanding, creation, use, and sustainment of engineered systems to enable the realization of stakeholder needs. Disciplines that use a systems approach (like systems engineering (SE)) consider an engineered system context that defines stakeholder needs, and look for the best ways to provide value by applying managed technical activities to one or more selected engineered systems of interest (SoI).

Generally, four specific types of engineered system contexts are recognized in SE:

- product system
- service system
- enterprise system
- system of systems (SoS) capability

One of the key distinctions between these system contexts pertains to the establishment of how and when the SoI boundary is drawn.

Engineered System-of-Interest

We use the idea of an engineered system context to define an engineered SoI and to capture and agree on the important relationships between it, the systems with which it works directly, and any other systems with which it works. All applications of a systems approach (and hence of SE) are applied in a system context rather than only to an individual system.

A system context can be constructed around the following set of open system relationships (Flood and Carson 1993):

- The **Narrower System-of-Interest** (NSoI) is the system of direct concern to the observer. The focus of this system is driven by the scope of authority or control with implicit recognition that this scope may not capture all related elements.
- The **Wider System-of-Interest** (WSoI) describes a logical system boundary containing all of the elements needed to fully understand system behavior. The observer may not have authority over all of the elements in the WSoI but will be able to establish the relationships between WSoI elements and NSoI elements.
- The WSoI exists in an **environment**. The immediate environment contains engineered, natural, and/or social systems, with which the WSoI (and thus some elements of the NSoI) directly interact for the purpose of exchanging material, information, and/or energy to achieve its goals or objective.
- A **Wider Environment** completes the context and contains systems that have no direct interaction with the SoI, but which might influence decisions related to it during its life cycle.

- "Some Theoretical Considerations of Mathematical Modeling" (Flood 1987) extends this context to include a **meta-system** (MS) that exists outside of the WSoI and exercises direct control over it.

The choice of the SoI boundary for particular activities depends upon what can be changed and what must remain fixed. The SoI will always include one or more NSoI but may also include WSoI and an MS if appropriate, such as when considering a service or an enterprise system.

Applying the System Context

For lower-level and less-complex systems, the WSoI can represent levels of a product system hierarchy. An example of this would be an engine management unit as part of an engine, or an engine as part of a car. The WSoI in a system context may encapsulate some aspects of SoS ideas for sufficiently complex systems. In these cases, the WSoI represents a collection of systems with their own objectives and ownership with which the NSoI must cooperate in working towards a shared goal. An example of this would be a car and a driver contributing to a transportation service.

This view of a SoS context being used as a means to support the engineering of an NSoI product system is one way in which a systems approach can be applied. It can also be applied directly to the SoS. Examples of this include a flexible multi-vehicle transportation service or transportation as part of a commercial enterprise. In this case, the NSoI aspect of the context no longer applies. The WSoI will consist of a set of cooperating systems, each of which might be changed or replaced to aid in the synthesis of a solution. The context may also need to represent **loose coupling**, with some systems moving in or out of the context depending on the need, or **late binding** with systems joining the context only at, or close to, the delivery of the service.

Thus, a context allows a reductionist view of the SoI that is of direct concern to an observer, as it provides for the system relationships and influences that are needed to maintain a holistic view of the consequence of any actions taken.

Product System Context

The distinction between a product and a product system is discussed in the article Engineered Systems.

A product system context would be one in which the SoI is the product itself. The wider system context for a product system can be a higher level of product hierarchy, a service, or an enterprise system that uses the product directly to help provide value to the user. A significant aspect of a product systems context is the clear statement of how the product is intended to be used and ensures that this information is given to the acquirer upon delivery. The customer will be required to accept the system, typically through a formal process, agreeing not to go against the terms of use.

If a systems approach is applied to a product context, it is done with the purpose of engineering a narrow system product to be integrated and used in a wider system product hierarchy or to enable the delivery of a wider system service directly to a user by an enterprise.

This view of the relationship between product and service is specific to product systems engineering. While some engineering of the acquirer's static service system may occur, it is done with a product focus. The definition of service system in a service systems engineering context describes a more dynamic view of service systems.

Service System Context

Services are activities that cause a transformation of the state of an entity (people, product, business, and region or nation) by mutually agreed terms between the service provider and the customer (Spohrer 2008). The distinction between service and a service system is discussed in the article Engineered Systems.

A service system context is one in which the SoI is the service system. This SoI contains all of the technology, infrastructure, people, resources, etc. that are needed to enable the service. The WSoI describes the enterprise providing the service as well as its relationship with other services that impact the success of the enterprise.

If a systems approach is applied to a service system, it is done with the purpose of engineering a service system to enable the outcomes required by an enterprise to satisfy its clients. When operating in the service system context, all options to provide the service must be considered, providing that they fit within the constraints of the enterprise. This will include interfaces to other services, people, and resources in the enterprise. If an option for providing the service makes use of existing products or resources within or outside of the enterprise, it must be ensured that they are available for this use and that this does not adversely affect other services. Part of getting the right service may require the negotiation of changes to the wider enterprise context, but this must be by agreement with the relevant authority.

For a service system, and also when considering the service system context, the value is realized only through service transactions. The end-user co-creates value at the time of the request to use the service. For example, to make a flight reservation using a smart phone, the service system is composed of many service system entities (the caller, the person called, the smart phone, the access network, the core Internet Protocol (IP) network, the Internet Service provider (ISP), the World Wide Web (WWW), data centers, etc. All these are necessary to enable the service. When a caller makes a reservation and then books the flight, the value has been created.

This definition of a service system, as associated with dynamic Information Technology (IT) services, is discussed further in the article Service Systems Engineering.

Enterprise System Context

The distinction between an enterprise and an enterprise system is discussed in the article Engineered Systems.

An enterprise system context is one in which the SoI is the enterprise system. This system contains all of the technology, infrastructure, people, resources, etc. needed to enable the service. The WSoI describes the business environment within which the enterprise sits.

It is to be noted that an enterprise context is not equivalent to an **organization** according to this definition. An enterprise includes not only the organizations that participate in it, but also the people, knowledge, and other assets, such as processes, principles, policies, practices, doctrines, theories, beliefs, facilities, land, and intellectual property that compose the enterprise.

An enterprise may contain or employ service systems along with product systems. An enterprise might even contain sub-enterprises. Enterprise systems are unique when compared to product and service systems in that:

- they are constantly evolving
- they rarely have detailed configuration controlled requirements
- they typically have (constantly changing) goals of providing shareholder value and customer satisfaction
- they exist in a context (or environment) that is ill-defined and constantly changing

The enterprise systems engineer must consider and account for these factors in their processes and methods.

Both product and service systems require an enterprise system context to create them and an enterprise to use the product system and deliver services, either internally to the enterprise or externally to a broader community. Thus, the three types of engineered system contexts are linked in all instances, regardless of which type of system the developers consider as the object of the development effort that is delivered to the customer.

-

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the identification and exploration of problems or opportunities in detail. The problem situations described by the activities in this topic may form a starting point for Synthesizing Possible Solutions. Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this knowledge area, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

The phrase "problem or opportunity" used herein recognizes that the "problem" is not always a negative situation and can also be a positive opportunity to improve a situation.

Introduction

According to Jenkins (1969), the first step in the systems approach is “the recognition and formulation of the problem.” The systems approach described in the Guide to the SE Body of Knowledge (SEBoK) is predominantly a hard system approach. The analysis, synthesis, and proving parts of the approach assume a problem or opportunity has been identified and agreed upon and that a "new" engineered system solution is needed.

However, the systems approach does not have to apply to the development and use of a newly designed and built technical solution. Abstract or experimental solutions to potential problems might be explored to help achieve agreement on a problem context. Solutions may involve reorganizing existing systems of systems (SoS) contexts or the modification or re-use of existing products and services. The problem and opportunity parts of the approach overlap with soft system approaches. This is discussed in more detail below.

One thing that must be considered in relation to system complexity is that the opportunity situation may be difficult to fully understand; therefore, system solutions may not solve the problem the first time, but is still useful in increasing the understanding of both problem issues and what to try next to work toward a solution.

Hence, problem exploration and identification is often not a one-time process that specifies the problem, but is used in combination with solution synthesis and analysis to progress toward a more complete understanding of problems and solutions over time (see Applying the Systems Approach for a more complete discussion of the dynamics of this aspect of the approach).

Problem Exploration

Soft system thinking does not look for "the problem," but considers a problematic situation. Forming systems views of this situation can help stakeholders better understand each other's viewpoints and provide a starting point for directed intervention in the current system context. If a full soft systems intervention is undertaken, such as a soft systems methodology (SSM) (Checkland 1999), it will not include formal analysis, synthesis, and proving. However, the SSM method was originally based on hard methodologies, particularly one presented by Jenkins (1969). It follows the basic principles of a systems approach: "analyzing" conceptual models of shared understanding, "synthesizing" intervention strategies, and "proving" improvements in the problematic situation.

Often, the distinction between hard and soft methods is not as clear cut as the theory might suggest. Checkland himself has been involved in applications of SSM as part of the development of information system design (Checkland and Holwell 1998). It is now agreed upon by many that while there is a role for a "pure soft system" approach, the service and enterprise problems now being tackled can only be dealt with successfully by a combination of soft problematic models and hard system solutions. Mingers and White (2009) give a number of relevant examples of this. In particular, they reference "Process and Content: Two Ways of Using SSM" (Checkland and Winters 2006). It is likely in the future that engineered system problems will be stated, solved, and used as part of a predominately soft intervention, which will place pressure on the speed of development needed in the solution space. This is discussed more fully in the topic Life Cycle Models.

The critical systems thinking and multi-methodology approaches (Jackson 1985) take this further by advocating a "pick and mix" approach, in which the most appropriate models and techniques are chosen to fit the problem rather than following a single methodology (Mingers and Gill 1997). Thus, even if the hard problem identification approach described below is used, some use of the soft system techniques (such as rich pictures, root definitions, or conceptual models) should be considered within it.

Problem Identification

Hard system thinking is based on the premise that a problem exists and can be stated by one or more stakeholders in an objective way. This does not mean that hard systems approaches start with a defined problem. Exploring the potential problem with key stakeholders is still an important part of the approach.

According to Blanchard and Fabrycky (2006, 55-56), defining a problem is sometimes the most important and difficult step. In short, a system cannot be defined unless it is possible to clearly describe what it is supposed to accomplish.

According to Edson (2008, 26-29), there are three kinds of questions that need to be asked to ensure we fully understand a problem situation. First, how difficult or well understood is the problem? The answer to this question will help define the tractability of the problem. Problems can be "tame," "regular," or "wicked":

- For tame problems, the solution may be well-defined and obvious.
- Regular problems are those that are encountered on a regular basis. Their solutions may not be obvious, thus serious attention should be given to every aspect of them.
- Wicked problems (Rittel and Webber 1973) cannot be fully solved, or perhaps even fully defined. Additionally, with wicked problems, it is not possible to understand the full effect of applying systems to the problem.

Next, who or what is impacted? There may be elements of the situation that are causing the problem, elements that are impacted by the problem, and elements that are just in the loop. Beyond these factors, what is the environment and what are the external factors that affect the problem? In examining these aspects, the tools and methods of systems thinking can be productively applied.

Finally, what are the various viewpoints of the problem? Does everyone think it is a problem? Perhaps there are conflicting viewpoints. All these viewpoints need to be defined. Persons affected by the system, who stand to benefit from the system, or can be harmed by the system, are called stakeholders. Wasson (2006, 42-45) provides a comprehensive list of stakeholder types. The use of soft systems models, as discussed above, can play an important part in this. Describing a problem using situation views can be useful when considering these issues, even if a single problem perspective is selected for further consideration.

Operations research is a hard systems method which concentrates on solving problem situations by deploying known solutions. The problem analysis step of a typical approach asks questions about the limitation and cost of the current system to identify efficiency improvements that need to be made (Flood and Carson 1993).

Traditional SE methods tend to focus more on describing an abstract model of the problem, which is then used to develop a solution that will produce the benefits stakeholders expect to see (Jenkins 1969). The expectation is often that a new solution must be created, although this need not be the case. Jenkins suggests that SE is just as applicable to a redesign of existing systems. A clear understanding of stakeholder expectations in this regard should produce a better understanding of part of the problem. Do stakeholders expect a new solution or modifications to their existing solutions, or are they genuinely open to solution alternatives which consider the pros and cons of either? Such expectations will influence suggestions of solution alternatives, as discussed in the Synthesizing Possible Solutions article.

An important factor in defining the desired stakeholder outcomes, benefits, and constraints is the operational environment, or scenario, in which the problem or opportunity exists. Armstrong (2009, 1030) suggests two scenarios: the first is the descriptive scenario, or the situation as it exists now, and the second is the normative scenario, or the situation as it may exist sometime in the future.

All of these aspects of problem understanding can be related to the concept of a system context.

Problem Context

The Engineered System Context topic identifies a way by which a complex system situation can be resolved around a system-of-interest (SoI). The initial identification of a "problem context" can be considered as the outcome of this part of the systems approach.

The systems approach should not consider only soft or hard situations. More appropriately, a problem or opportunity should be explored using aspects of both. In general, the application of the systems approach with a focus on engineered system contexts will lead to hard system contexts in which an identified SoI and required outcome can be defined.

An initial description of the wider SoI and environment serves as the problem or opportunity problem scope. Desired stakeholder benefits are expressed as outcomes in the wider system and some initial expression of what the SoI is intended for may be identified. Jenkins (1969) defines a problem formulation approach where one:

- states the aim of the SoI
- defines the wider SoI
- defines the objectives of the wider SoI
- defines the objectives of the system
- defines economic, informational, and other conditions

In a hard system problem context, a description of a logical or ideal system solution may be included. This ideal system cannot be implemented directly, but describes the properties required of any realizable system solution.

To support this problem or opportunity description, a soft context view of the SoI will help ensure wider stakeholder concerns are considered. If a soft system context has been defined, it may include a conceptual model (Checkland 1999) which describes the logical elements of a system that resolve the problem situation and how they are perceived by different stakeholders. Unlike the hard system view, this does not describe the ideal solution, but provides an alternative view on how aspects of any solution would be viewed by potential stakeholders.

In problem contexts with a strong coercive dimension, the problem context should include an identification of the relative power and the importance of stakeholders.

The problem context should include some boundaries on the cost, time to deployment, time in use, and operational effectiveness needed by stakeholders. In general, both the full problem context and an agreed version of the problem to be tackled next are described. (See Applying the Systems Approach.)

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the synthesis of possible solution options in response to the problem situations described by activities from Identifying and Understanding Problems and Opportunities topic. The solution options proposed by the synthesis activities will form the starting point for the Analysis and Selection between Alternative Solutions. Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this KA, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

Synthesis Overview

System synthesis is an activity within the systems approach that is used to describe one or more system solutions based upon a problem context for the life cycle of the system to:

- Define options for a SoI with the required properties and behavior for an identified problem or opportunity context.
- Provide solution options relevant to the SoI in its intended environment, such that the options can be assessed to be potentially realizable within a prescribed time limit, cost, and risk described in the problem context.
- Assess the properties and behavior of each candidate solution in its wider system context.

The iterative activity of system synthesis develops possible solutions and may make some overall judgment regarding the feasibility of said solutions. The detailed judgment on whether a solution is suitable for a given iteration of the systems approach is made using the Analysis and Selection between Alternative Solutions activities.

Essential to synthesis is the concept of holism(Hitchins 2009), which states that a system must be considered as a whole and not simply as a collection of its elements. The holism of any potential solution system requires that the behavior of the whole be determined by addressing a system within an intended environment and not simply the accumulation of the properties of the elements. The latter process is known as reductionism and is the opposite of holism, which Hitchins (2009, 60) describes as the notion that "the properties, capabilities, and behavior of a system derive from its parts, from interactions between those parts, and from interactions with other systems."

When the system is considered as a whole, properties called emergent properties often appear (see Emergence). These properties are often difficult to predict from the properties of the elements alone. They must be evaluated within the systems approach to determine the complete set of performance levels of the system. According to Jackson (2010), these properties can be considered in the design of a system, but to do so, an iterative approach is required.

In complex systems, individual elements will adapt to the behavior of the other elements and to the system as a whole. The entire collection of elements will behave as an organic whole. Therefore, the entire synthesis activity, particularly in complex systems, must itself be adaptive.

Hence, synthesis is often not a one-time process of solution design, but is used in combination with problem understanding and solution analysis to progress towards a more complete understanding of problems and solutions over time (see Applying the Systems Approach topic for a more complete discussion of the dynamics of this aspect of the approach).

Problem or Opportunity Context

System synthesis needs the problem or opportunity that the system is intended to address to have already been identified and described and for non-trivial systems, the problem or opportunity needs to be identified and understood concurrently with solution synthesis activities.

As discussed in Identifying and Understanding Problems and Opportunities, the systems approach should not consider strictly soft or hard situations. In general, the application of the systems approach, with a focus on engineered system contexts, will lead to hard system contexts in which an identified SoI and required outcome are defined. Even in these cases, a soft context view of the SoI context will help ensure wider stakeholder concerns are considered.

The problem context should include some boundaries on the cost, time to deployment, time in use, and operational effectiveness needed by stakeholders. In general, the goal is not to synthesize the perfect solution to a problem, but rather to find the best available solution for the agreed version of the problem.

Synthesis Activities

The following activities provide an outline for defining the SoI: grouping of elements, identification of the interactions among the elements, identification of interfaces between elements, identification of external interfaces to the SoI boundary and common sub-elements within the SoI boundary.

The activities of systems synthesis are built on the idea of a balanced reduction vs. holism approach as discussed in What is Systems Thinking? topic. It is necessary to divide system elements and functions to create a description of the SoI which is realizable, either through combinations of available elements or through the design and construction of new elements. However, if the system is simply decomposed into smaller and smaller elements, the holistic nature of systems will make it more and more difficult to predict the function and behavior of the whole. Thus, synthesis progresses through activities that divide, group, and allocate elements, and then assesses the complete system's properties in context relevant to the user need the SoI will fulfill. Hence, synthesis occurs over the entire life cycle of the system as the system and its environment change.

Identification of the Boundary of a System

Establishing the boundary of a system is essential to synthesis, the determination of the system's interaction with its environment and with other systems, and the extent of the SoI. Buede (2009, 1102) provides a comprehensive discussion of the importance of, and methods of, defining the boundary of a system in a SE context.

Identification of the Functions of the System

The function of a system at a given level of abstraction is critical to synthesis since the primary goal of the synthesis activity is to propose realizable system descriptions which can provide a given function. The function of a system is distinct from its behavior as it describes what the system can be used for or is asked to do in a larger system context.

Buede (2009, 1091-1126) provides a comprehensive description of functional analysis in a SE context.

Identification of the Elements of a System

System synthesis calls for the identification of the elements of a system. Typical elements of an Engineered System Context may be physical, conceptual, or processes. Physical elements may be hardware, software, or humans. Conceptual elements may be ideas, plans, concepts, or hypotheses. Processes may be mental, mental-motor (writing, drawing, etc.), mechanical, or electronic (Blanchard and Fabrycky 2006, 7).

In addition to the elements of the system under consideration (i.e., a SoI), ISO 15288 (ISO/IEC/IEEE 15288 2015) also calls for the identification of the enabling systems. These are systems (or services) utilized at various stages in the life cycle, e.g., development, utilization or support stages, to facilitate the SoI in achieving its objectives.

Today's systems often include existing elements. It is rare to find a true "greenfield" system, in which the developers can specify and implement all new elements from scratch. "Brownfield" systems, wherein legacy elements constrain the system structure, capabilities, technology choices, and other aspects of implementation, are much more typical (Boehm 2009).

Division of System Elements

System synthesis may require elements to be divided into smaller elements. The division of elements into smaller elements allows the systems to be grouped and leads to the SE concept of physical architecture, as described by Levin (2009, 493-495). Each layer of division leads to another layer of the hierarchical view of a system. As Levin points out, there are many ways to depict the physical architecture, including the use of wiring diagrams, block diagrams, etc. All of these views depend on arranging the elements and dividing them into smaller elements. According to the principle of recursion, these decomposed elements are either terminal elements, or are decomposable. The hierarchical view does not imply a top-down analytical approach to defining a system. It is

simply a view. In the systems approach, levels of the hierarchy are defined and considered recursively with one level forming the context for the next.

Grouping of System Elements

System synthesis may require that elements be grouped. This leads to the identification of the sub-systems that are essential to the definition of a system. Synthesis determines how a system may be partitioned and how each sub-system fits and functions within the whole system. The largest group is the SoI, also called the relevant system by Checkland (1999, 166). According to Hitchins, some of the properties of a SoI are as follows: the SoI is open and dynamic, the SoI interacts with other systems, and the SoI contains sub-systems (Hitchins 2009, 61). The SoI is brought together through the concept of synthesis.

Identification of the Interactions among System Elements

System synthesis may require the identification of the interactions among system elements. These interactions lead to the SE process of interface analysis. Integral to this aspect is the principle of interactions. Interactions occur both with other system elements as well as with external elements and the environment. In a systems approach, interfaces have both a technical and managerial importance. Managerial aspects include the contracts between interfacing organizations. Technical aspects include the properties of the physical and functional interfaces. Browning provides a list of desirable characteristics of both technical and managerial interface characteristics (Browning 2009, 1418-1419) .

System synthesis will include activities to understand the properties of system elements, the structure of proposed system solutions, and the resultant behavior of the composed system. A number of system concepts for describing system behavior are discussed in the Concepts of Systems Thinking topic. It should be noted that in order to fully understand a system's behavior, we must consider the full range of environments in which it might be placed and its allowable state in each. According to Page, in complex systems, the individual elements of the system are characterized by properties which enhance the systems as a whole, such as their adaptability (Page 2009).

Defining the System-of-Interest

Flood and Carson provide two ways to identify system boundaries: a bottom-up, or **structural approach**, which starts with significant system elements and builds out, and a top down, or **behavioral approach**, in which major systems needed to fulfill a goal are identified and then the work flows downward (Flood and Carson 1993). They identify a number of rules proposed by Beishon (1980) and Jones (1982) to help in the selection of the best approach.

In either case, the ways in which system elements are refined, grouped, and allocated must be driven towards the synthesis of a realizable system solution description. A realizable solution must consider elements that are either already available, can be created from existing system elements, or are themselves described as system contexts which will need to be synthesized at a future point. In the third case, it is one of the outcomes of the Analysis and Selection between Alternative Solutions activities that is used to assess the risk that a given element may not be able to be synthesized in the required time limit or cost budget.

A top down approach might start with a system boundary and an overall description of system functions. Through the repeated application of element identification, division, grouping, and allocation of functions, a complete description of the elements needed for the SoI can be defined. In this case, the choice of system elements and allocation of functions may be guided by pre-defined ways of solving a given problem or by identified system patterns; both can support as well as insert bias into the synthesis. For example, one might start with the need to provide energy to a new housing project and propose solution options based around connections to an existing power grid, local power generators, renewable energy sources, increased energy efficiency, etc.

The iterative nature of analysis also reflects the need to change the solution as the life cycle progresses and changes the system's environment; thereby, possibly changing what a "best" solution is.

A bottom up approach starts with major elements and interactions. Again, division, grouping, and identification allows for the construction of a full system description that is capable of providing all the necessary functions, at which point the final SoI boundary can be set. In this case, the choice of system elements and groupings will be driven by the goal of ensuring that the major system elements can be formed together into a viable system whole. For example, there may be a need to replace an existing delivery vehicle and produce solution options that consider vehicle ownership/leasing, driver training, petrol, diesel or electric fuel, etc.

The systems approach aspect of synthesis leads to SE terms such as “design” and “development.” Wasson describes synthesis from a SE point of view (Wasson 2006, 390-690). White provides a comprehensive discussion of methods of achieving design synthesis (White 2009, 512-515). The systems approach treats synthesis at the abstract level while the SE process definitions provide the concrete steps.

The SoI brings together elements, sub-systems and systems through the concept of synthesis to identify a solution option.

Synthesis of possible solutions may result in the development of artifacts documenting the synthesis itself and provide the basis for analysis and selection between alternative solutions. These artifacts are dynamic and will change as the SoI changes its environment throughout the system life cycle.

-

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the analysis and selection of a preferred solution from the possible options, which may have been proposed by Synthesizing Possible Solutions. Selected solution options may form the starting point for Implementing and Proving a Solution. Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this KA, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

System Analysis

System analysis is an activity in the systems approach that evaluates one or more system artifacts created during the activities involved in Synthesizing Possible Solutions, such as:

- Defining assessment criteria based on the required properties and behavior of an identified problem or opportunity system situation.
- Accessing the properties and behavior of each candidate solution in comparison to the criteria.
- Comparing the assessments of the candidate solutions and identification of any that could resolve the problem or exploit the opportunities, along with the selection of candidates that should be further explored.

As discussed in Synthesizing Possible Solutions topic, the problem context for an engineered system will include a logical or ideal system solution description. It is assumed that the solution that "best" matches the ideal one will be the most acceptable solution to the stakeholders. Note, as discussed below, the "best" solution should include an understanding of cost and risk, as well as effectiveness. The problem context may include a soft system conceptual model describing the logical elements of a system to resolve the problem situation and how these are perceived by different stakeholders (Checkland 1999). This soft context view will provide additional criteria for the analysis process, which may become the critical issue in selecting between two equally effective solution alternatives.

Hence, analysis is often not a one-time process of solution selection; rather, it is used in combination with problem understanding and solution synthesis to progress towards a more complete understanding of problems and solutions over time (see Applying the Systems Approach topic for a more complete discussion of the dynamics of this aspect of the approach).

Effectiveness Analysis

Effectiveness studies use the problem or opportunity system context as a starting point.

The effectiveness of a synthesized system solution will include performance criteria associated with both the system's primary and enabling functions. These are derived from the system's purpose, in order to enable the realization of stakeholder needs in one or more, wider system contexts.

For a product system, there are a set of generic non-functional qualities that are associated with different types of solution patterns or technology, e.g., safety, security, reliability, maintainability, usability, etc. These criteria are often explicitly stated as parts of the domain knowledge of related technical disciplines in technology domains.

For a service system or enterprise system, the criteria will be more directly linked to the identified user needs or enterprise goals. Typical qualities for such systems include agility, resilience, flexibility, upgradeability, etc.

In addition to assessments of the absolute effectiveness of a given solution system, systems engineers must also be able to combine effectiveness with the limitations of cost and timescales included in the problem context. In general, the role of system analysis is to identify the proposed solutions which can provide some effectiveness within the cost and time allocated to any given iteration of the systems approach (see Applying the Systems Approach for details). If none of the solutions can deliver an effectiveness level that justifies the proposed investment, then it is necessary to return to the original framing of the problem. If at least one solution is assessed as sufficiently effective, then a choice between solutions can be proposed.

Trade-Off Studies

In the context of the definition of a system, a trade-off study consists of comparing the characteristics of each candidate system element to those of each candidate system architecture in order to determine the solution that globally balances the assessment criteria in the best way. The various characteristics analyzed are gathered in cost analysis, technical risks analysis, and effectiveness analysis (NASA 2007). To accomplish a trade off study, there are a variety of methods, often supported by tooling. Each class of analysis is the subject of the following topics:

- Assessment criteria are used to classify the various candidate solutions. They are either absolute or relative. For example, the maximum cost per unit produced is c$, cost reduction shall be x%, effectiveness improvement is y%, and risk mitigation is z%.
- **Boundaries** identify and limit the characteristics or criteria to be taken into account at the time of analysis (e.g., the kind of costs to be taken into account, acceptable technical risks, and the type and level of effectiveness).
- **Scales** are used to quantify the characteristics, properties, and/or criteria and to make comparisons. Their definition requires knowledge of the highest and lowest limits, as well as the type of evolution of the characteristic (linear, logarithmic, etc.).
- An assessment score is assigned to a characteristic or criterion for each candidate solution. The goal of the trade-off study is to succeed in quantifying the three variables (and their decomposition in sub-variables) of cost, risk, and effectiveness for each candidate solution. This operation is generally complex and requires the use of models.
- The **optimization** of the characteristics or properties improves the scoring of interesting solutions.

A decision-making process is not an accurate science; ergo, trade-off studies have limits. The following concerns should be taken into account:

- Subjective Criteria – personal bias of the analyst; for example, if the component has to be beautiful, what constitutes a “beautiful” component?
- Uncertain Data – for example, inflation has to be taken into account to estimate the cost of maintenance during the complete life cycle of a system; how can a systems engineer predict the evolution of inflation over the next five years?
- Sensitivity Analysis – A global assessment score that is designated to every candidate solution is not absolute; thus, it is recommended that a robust selection is gathered by performing a sensitivity analysis that considers small variations of assessment criteria values (weights). The selection is robust if the variations do not change the order of scores.

A thorough trade-off study specifies the assumptions, variables, and confidence intervals of the results.

Systems Principles of System Analysis

From the discussions above, the following general principles of systems analysis can be defined:

- Systems analysis is an iterative activity consisting of trade studies made between various solution options from the systems synthesis activity.
- Systems analysis uses assessment criteria based upon a problem or opportunity system description.
  - These criteria will be based around an ideal system description that assumes a hard system problem context can be defined.
  - The criteria must consider required system behavior and properties of the complete solution in all of the possible wider system contexts and environments.
  - Trade studies require equal consideration to the primary system and the enabling system working as a single system to address the user need. These studies need to consider system requirements for Key Performance Parameters (KPPs), systems safety, security, and affordability across the entire life cycle.
  - This ideal system description may be supported by soft system descriptions from which additional “soft” criteria may be defined (e.g., a stakeholder preference for or against certain kinds of solutions and relevant social, political, or cultural conventions to be considered in the likely solution environment, etc.).
- At a minimum, the assessment criteria should include the constraints on cost and time scales acceptable to stakeholders.
- Trade studies provide a mechanism for conducting analysis of alternative solutions.

- A trade study should consider a "system of assessment criteria," designating special attention to the limitations and dependencies between individual criteria.
- Trade studies need to deal with both objective and subjective criteria. Care must be taken to assess the sensitivity of the overall assessment to particular criteria.

PROJECT PERFORMANCE INTERNATIONAL

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the implementation and proving of a preferred solution that may have been selected by activities described in the Analysis and Selection between Alternative Solutions topic. The activities that apply to an implemented solution during its operational life are described in Deploying, Using, and Sustaining Systems to Solve Problems topic, and how systems fit into commercial and acquisition relationships is discussed in the Introduction to System Fundamentals topic. Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this KA, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

Proving the System Overview

This topic covers both the sub-topics of verification and validation.

Verification

Verification is the determination that each element of the system meets the requirements of a documented specification (see principle of elements). Verification is performed at each level of the system hierarchy. In the systems approach, this topic pertains to the more abstract level of providing evidence that the system will accomplish what it was meant to do. In SE, this topic pertains to providing quantitative evidence from tests and other methods for verifying the performance of the system.

Validation

Validation is the determination that the entire system meets the needs of the stakeholders. Validation only occurs at the top level of the system hierarchy. In the systems approach, this topic pertains to the more abstract level of ensuring the system meets the needs of the stakeholders. In SE, this topic pertains to the detailed demonstrations and other methods that are used to promote stakeholder satisfaction.

In a SE context, Wasson provides a comprehensive guide to the methods of both system verification and system validation (Wasson 2006, 691-709).

-

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It describes knowledge related to the deployment, sustainment, and use of a solution that may have been developed through the activities described in the Implementing and Proving a Solution topic. Discussion of how a deployed system fits into commercial and acquisition relationships is present in Introduction to System Fundamentals. Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this KA, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

Introduction

Part 3, Systems Engineering and Management, of the Guide to the SE Body of Knowledge (SEBoK) provides two additional KAs that address the engineering aspects of these steps of the systems approach. KAs Product and Service Life Management and System Deployment and Use in Part 3 explain the SE aspects of deployment, operation, maintenance, logistics, service life extension, updates, upgrades, disposal and the retirement of systems.

A systems approach considers the total system and the total life cycle of the system. This includes all aspects of the system and the system throughout its life until the day users depose of the system and the external enterprises complete the handling of the disposed system products. Creation of the system is rarely the step that solves the stakeholders' problems. It is the use of the system solution that solves the problem. From this perspective the deployment, use and sustainment of the system are important concepts that must be a part of the systems approach.

Engineered systems are eventually owned by an individual, team, or enterprise. Those who own the system during development may not be the ones who own the system when it is in operation. Moreover, the owners may not be the users; e.g., service systems may be used by the general public but owned by a specific business that offers the service. The transition of a system from development to operations is often itself a complex task, involving such activities as training those who will operate the system, taking legal actions to complete the transfer, and establishing logistical arrangements so that the operators can keep the system running once the transition is completed.

A complete systems approach must also consider the many enterprises involved in the system from initial conception through the completion of the disposal process. These enterprises are all stakeholders with requirements, which all have interfaces that must be considered as part of a total systems approach.

There is very little in the literature pertaining to the application of the systems approach to these phases of the life cycle. However, a basic premise of this KA is that the systems approach pertains to all phases of a system's life

cycle. Hence, to properly build systems to solve problems or for other uses, it can be inferred that the systems approach pertains to the deployment, use, and the sustainment of the systems. Many of the available references in this topic area are from SE literature rather than from literature associated with the systems approach; the reader should also see Part 3 of the SEBoK, Systems Engineering and Management.

Deployment: The Transition from Development to Operation

Transferring custody of the SoI and responsibility for its support from one organization to another occurs during deployment and is often called transition (INCOSE 2011). Transition of a product system includes the integration of the system into the acquiring organization's infrastructure. Deployment and transition involves the activity of moving the system from the development to the operational location(s), along with the support systems necessary to accomplish the relocation.

Transition includes the initial installation of a system and the determination that it is compatible with the wider system and does not cause any significant wider system issues. This process of acceptance and release for use varies between domains and across businesses and enterprises, and can be thought of as an initial assessment of the system's effectiveness (Hitchins 2007). Generally, transition may be considered as having two parts: 1.) ensuring that the new system interoperability with the systems around it and 2.) ensuring the resulting system is safe and possesses other critical operational properties.

It is particularly important to consider emergent properties when a new system is added to the existing organization's system of systems (SoS) network, as well as the complexity of the organization into which the new system is transitioned (see also Complexity). The more complex the receiving organization is, the more challenging the transition will be, and the greater the likelihood of unintended interactions and consequences from the new system's insertion. Dealing with the consequences of this complexity starts in transition and continues into operation, maintenance, and disposal.

Transition of a service system is often performed in two stages. First, the service system infrastructure is accepted and released. Second, each realization of the service is accepted and released. There can be significant problems during the second stage if the required responsiveness of the service does not leave sufficient time to ensure that the service meets necessary functional and quality attributes, including interoperability, safety, and security. (See Service Systems Engineering.)

Transition and deployment of a system may introduce unique requirements that are not necessary for operation or use. These requirements can influence the design of the system; therefore, must be considered during the initial requirements and design stages. The most common examples are related to the need to transport the system or system elements, which often limits the size and weight of the system elements.

Transition can also require its own enabling systems, each of which can be realized using a systems approach.

Use: Operation

Use of the system to help enable delivery of user services is often called "operations" (INCOSE 2011). A system's effectiveness is normally considered throughout the operational life of a system. For a complex system, emergent behavior should be considered in three ways:

- to identify and plan for emergent properties within the system realization process (See System Realization KA in Part 3, Systems Engineering and Management)
- to incorporate mechanisms for identifying and handling unexpected emergent properties within the system during its use
- to provide necessary procedures for dealing with wider system consequences of unexpected emergent properties in the enterprise (e.g., emergency responses or medical first aid)

Operations require their own enabling systems, each of which can be realized using a systems approach.

System Sustainment and Maintenance

System sustainment requires maintenance of the system throughout its useful life (INCOSE 2011). In system terms, maintenance implements systems that handle entropy and maintaining the SoI in a viable state. Since an open system maintains its existence by continual exchange of energy, information, and materiel with its environment, one aspect of its maintenance must be the management of resources in the environment.

Hitchins (2007) describes generic approaches to resource management and viability management based on systems concepts. Resource management identifies the need to consider the acquisition, storage, distribution, conversion, and disposal of resources. Viability management should consider systems to maintain homeostasis and a means for ensuring resilience to environmental disturbance and adaptability to environmental change.

Maintenance will require its own enabling systems, each of which can be realized using a systems approach. Maintenance success is more likely if it is considered as part of the system concept and design well before the system enters service.

Disposal

A total life cycle systems approach cannot be considered complete without consideration of how disposal of the system will be accomplished. The purpose of disposal is to remove a system element from the operational environment with the intent of permanently terminating its use, and remove any hazardous or toxic materials or waste products (INCOSE 2011).

During disposal, the entirety of the open system crosses the boundary from the system side to the environment. A complete systems approach must consider how it crosses the boundary and what remains that must be managed by enterprises other than the ones that developed, used or sustained the system. Including disposal in the system approach expands the stakeholders, the enterprises and the external systems that must be considered.

Disposal requires its own enabling systems, each of which can be realized using a systems approach. Some of these may be contained within the system boundaries and others may be external to the system. For the external disposal systems, the interface where the handover occurs must be considered. As with maintenance, a large part of successful disposal requires related issues to have been considered early on in the system's life cycle.

The topic Disposal and Retirement in Part 3, Systems Engineering and Management, of the SEBoK provides information on the engineering aspects of system disposal.

-

The systems approach relates to both the dynamics of problem resolution and stakeholder value over time, as well as to the levels of system relationship, detailed management, and the engineering activities this implies.

The "Systems Approach Applied to Engineered Systems" knowledge area is graciously sponsored by PPI.

This article builds on the concepts introduced in Overview of the Systems Approach topic. It is part of the Systems Approach Applied to Engineered Systems knowledge area (KA), which describes, primarily through five groups of activities, the application of an approach based around systems thinking to engineered system contexts throughout their lives.

Life Cycle

Engineered Systems provide outcomes which deliver benefits to stakeholders by helping them achieve something of value in one or more problem situations. Ultimately, a system is successful only if it enables successful outcomes for its stakeholders (Boehm and Jain 2006). In complex real world situations, value can best be provided through a continuing process of adapting the system needs and developing associated solutions in response to changing circumstances, according to the principle of **Progressive Satisfying** (Hitchins 2009).

A value cycle associating the systems approach to the delivery of real world stakeholder benefits is discussed in the Overview of the Systems Approach topic. A greater understanding of the value of an engineered system within its context enables agreement on the problem situation and appropriate system interventions to be created, deployed, and used overall, in turn enabling a more effective application of the systems approach. Value is fully realized only when considered within the context of time, cost, funding and other resource issues appropriate to key stakeholders (Ring 1998).

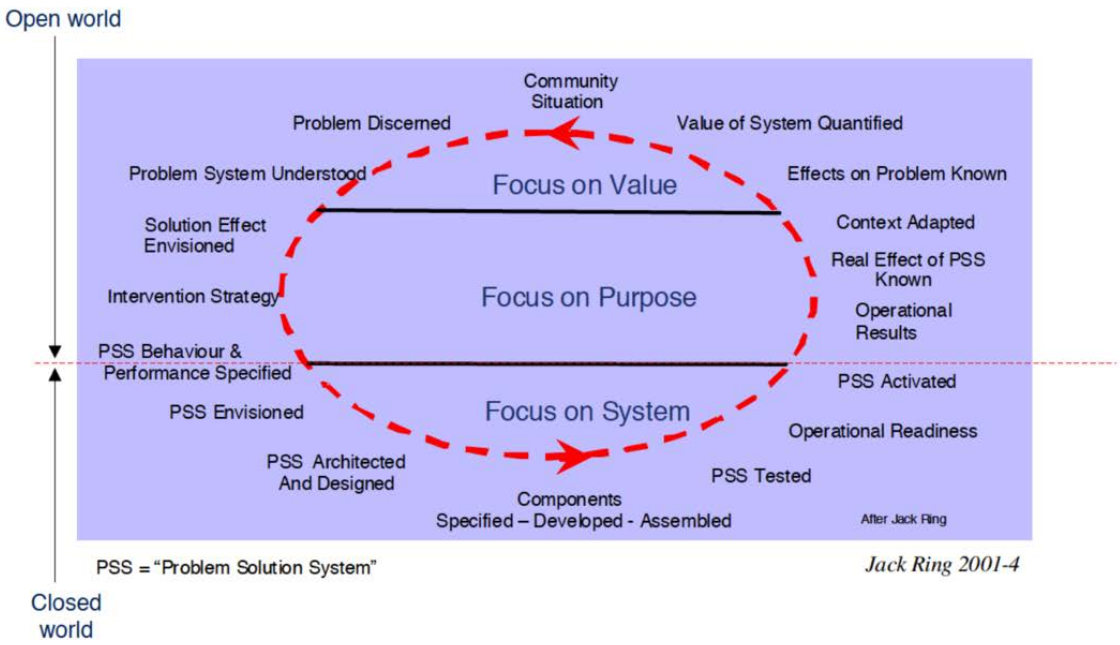

Figure 1. Ellipse Graphic (Ring 1998).

The views in Figure 1 apply the idea of **Systemic Intervention** to the resolution of problem situations in which one or more engineered system solutions might be required. For each turn of the cycle, an agreement is made between stakeholders and developers that an Engineered System to solve problem X with effectiveness Y in agreed conditions Z has a chance of delivering value A for which they are willing to invest cost B and other resources C.

It is in the nature of wicked problems that this proposition cannot be a certainty. life cycle approaches to understand and manage the shared risk of tackling such problems are discussed in Life Cycle Models. The idea of Systemic Intervention comes from soft systems thinking (see Systems Approaches).

For each of the engineered system problems, the solutions agreed above must be developed such that they are effective in terms of cost, performance and other properties relevant to the problem domain. A developer must consider not only what to do, but when and how much to do to provide real value (Senge 1990). In systems engineering (SE) and management practices, this leads to the two key concepts (INCOSE 2011):

- **Life Cycles:** Stakeholder value and problem resolution described as a set of life cycle stages over which problems can be explored and resolved, and resources can be managed.
- **Life Cycle Processes:** Systems of activities focused on creation and sharing of knowledge associated with the systems approach, that can be employed to promote a holistic approach over a life cycle.

Life cycle management provides the framework in which to take a systems approach to all aspects of an engineered system context, which includes not only the system product or service but also the systems to create, deploy and support it (Martin 2004). The following sections consider how the systems approach should be applied to an identified problem statement, within the context of the overall value cycle discussed above.

Application Principles

Concurrency

Within any application of the systems approach, the activities of problem identification, solution synthesis and selection, solution implementation and proving, and deployment, sustainment, and use should be applied concurrently, reflecting their interrelationships and dependencies.

The system value cycle (Ring 1998) can be taken as a generic model of the life of an engineered system within a problem resolution cycle driven by stakeholder value. For practical reasons, it is necessary to break this life down into a set of finite stages to allow activities to be organized. We can express the value cycle as six groups of questions to cycle around value, problem, and solution questions that are related to the systems approach:

1. What values do stakeholders want/need?
2. What system outcomes could improve this value?
3. What system can provide these outcomes?
4. How do we create such a system?
5. How do we deploy and use the system to achieve the outcomes?
6. Do these outcomes provide the expected improvement in value?

The above questions focus on each iteration of the systems approach to deliver stakeholder goals within an enterprise context. Activities 1 and 6 are part of the business cycles of providing stakeholder value within an enterprise, whereas activities 2 through 5 can be mapped directly to product, service, and enterprise engineering life cycles. A distinction is made here between the normal business of an enterprise and the longer-term strategic activities of Enterprise Systems Engineering.

The following diagram illustrates the concurrent nature of the activities of a systems approach over time.

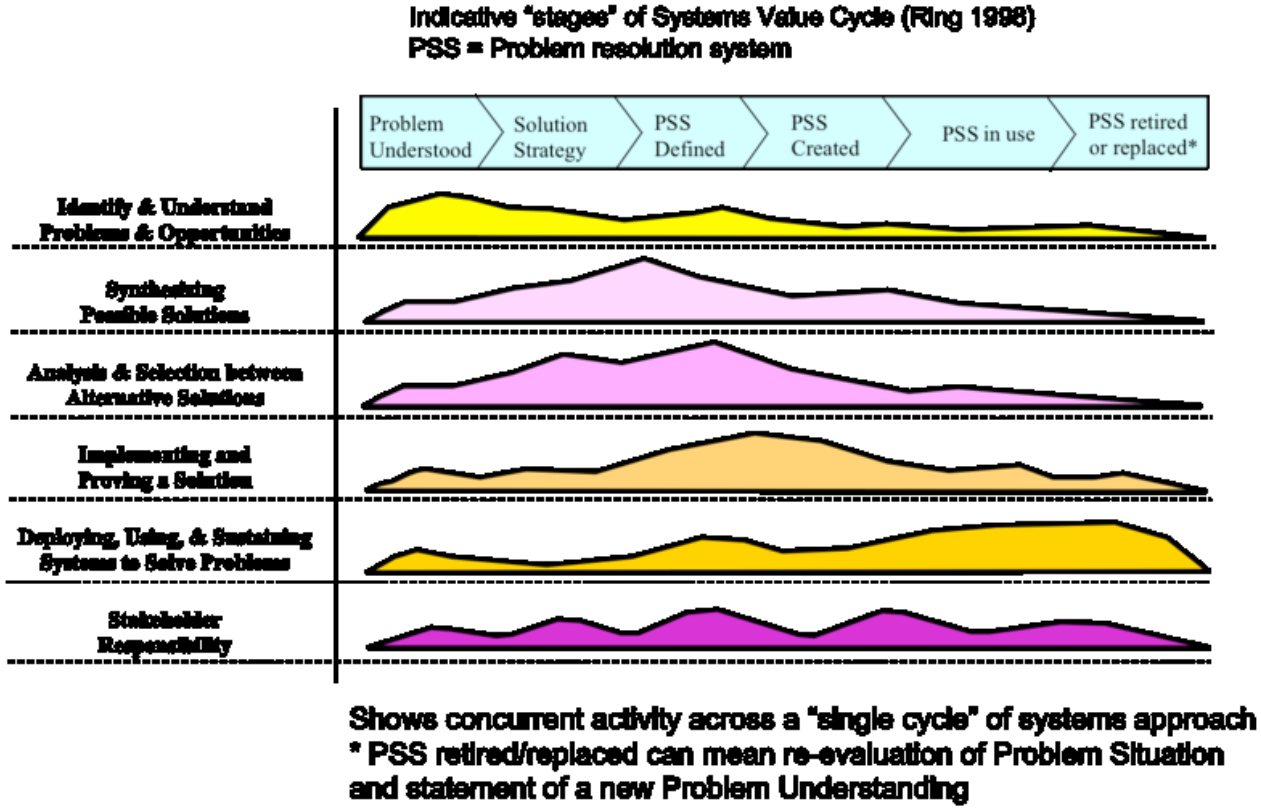

Figure 2. Activities of the Systems Approach Applied within a System Life Cycle. (SEBoK Original)

The lines on Figure 2 represent activity in each of the activity areas over a simple (not to scale) life cycle based on the questions above. Activities may have a primary focus in certain stages but need to span the whole of life to ensure a holistic approach. For example, problem identification has a large input during the Problem Understanding stage, but problems are refined, reviewed, and reassessed over the rest of the life cycle. Similarly, Implement and Proving activities are conducted during the transition from Create to Use. This is only possible if proving issues, strategies, and risks are considered in earlier stages. This diagram is a schematic representation of these activity mappings, sometimes called a hump diagram (Kruchten 2003).

For the generic systems approach, the following fundamental life cycle principles apply:

- A life cycle has groups of stages which cover understanding stakeholder value; exploration of a problem situation; creation of a system solution (see System Realization); and System Deployment and Use.
- Life cycle processes define a system of engineering and management activities based on the detailed information needed to ensure a systems approach across a life cycle (e.g., requirements, architecture, verification, and validation).
- Activities in any of the processes may be employed in all of the stages to allow for appropriate concurrency.
- The sequence and control of the life cycle stages and concurrent process activities must be tailored to the problem situation and commercial environment (Lawson 2010), thus leading to the selection of an appropriate life cycle model.
- Appropriate management activities must be included in the life cycle to ensure consideration of time, cost, and resource drivers.
- In focusing on the creation of a specific system-of-interest (SoI) to provide solutions within the cycle, it is important to recognize the need to employ the right balance between reductionism and holism by considering the appropriate system context.

The ways in which this idea of concurrent process activity across a life cycle has been implemented in SE are discussed in Systems Engineering and Management.

Iteration

The systems approach can be applied in an iterative way to move towards an acceptable solution to a problem situation within a larger cycle of stakeholder value.

The systems approach can be applied to multiple systems within an engineered system context, as discussed below. At each level, the approach may be applied iteratively to cycle between what is needed and versions of the solutions within a life cycle model.

Hitchins (2009) defines two principles related to iterations:

- **Adaptive Optimizing:** Continual redesign addresses the problem space, detecting and addressing changes in situation, operational environment, other interacting systems, and other factors; it continually conceives, designs, and implements or reconfigures the whole solution system to perform with optimal effectiveness in the contemporary operational environment.
- **Progressive Entropy Reduction:** Continual performance and capability improvement of systems in operation may be undertaken by customer or user organizations with or without support from industry, as they seek to “get the best” out of their systems in demanding situations. In terms of knowledge or information, this process involves progressively reducing entropy, going from a condition of high entropy (that is, disorder) at the outset to low entropy (order) at the finish.

In general, these two cycles of iterations can be realized from combinations of three life cycle types (Adcock 2005):

- Sequential: With iteration between the stages to solve detailed issues as they arise, a single application of the systems approach is sufficient.

- Incremental: Successive versions of the sequential approach are necessary for a solution concept. Each increment adds functionality or effectiveness to the growing solution over time.
- Evolutionary: A series of applications of the sequential approach for alternative solutions intended to both provide stakeholder value and increase problem understanding. Each evolutionary cycle provides an opportunity to examine how the solution is used so the lessons learned can be incorporated in the next iteration.

These aspects of the systems approach form the basis for life cycle models in Life Cycle Models.

Recursion

The stakeholder value, problem resolution, and system creation aspects of the system value cycle may each require the use of a focused systems approach. These might be soft systems to prove a better understanding of a situation, product systems and/or service systems solutions to operational needs, enabling systems to support an aspect of the product or service life cycle, or enabling systems used directly by the enterprise system.

Each of these systems may be identified as a system-of-interest (SoI) and require the application of the systems approach. This application may be sequential (the start of one system approach dependent on the completion of another) or parallel (independent approaches which may or may not overlap in time), but will often be recursive in nature.

Recursion is a technique borrowed from computer science. In computer science, recursion occurs when a function calls itself repeatedly to logically simplify an algorithm. In a recursive application applied to systems, the systems approach for one system-of-interest is nested inside another. Examples include cases where:

- trades made at one level of the system require trades to be made for system elements;
- the analysis of a system requires analysis of a system element;
- the synthesis of a solution system requires one or more sub-system elements; and
- the verification of a product system requires verification of system elements.

In each case, the “outer” system approach may continue in parallel with the “inner” to some extent but depends on key outcomes for its own progress.

As with all recursive processes, at some stage the application of the approach must reach a level at which it can be completed successfully. This then "rolls up" to allow higher levels to move forward and eventually complete all nested applications successfully.

The INCOSE *Systems Engineering Handbook* (INCOSE 2011) describes a recursive application of SE to levels of system element with each application representing a system project. Martin (1997) describes the recursive application of SE within a product system hierarchy until a component level is reached, at which point procurement of design and build processes can be used to create solution elements.

The principle of recursive application and how it relates to life cycle models is described in Life Cycle Models. This topic is part of the Systems Approach Applied to Engineered Systems knowledge area (KA). It summarizes various aspects of stakeholder responsibility for acquisition and ownership during the system life cycle processes covered by such sources as the International Council on Systems Engineering Handbook (INCOSE 2012). Any of the activities described below may also need to be considered concurrently with other activities in the systems approach at a particular point in the life of a system-of-interest (SoI).

The activities described below should be considered in the context of the Overview of the Systems Approach topic at the start of this KA. The final topic in this KA, Applying the Systems Approach, considers the dynamic aspects of how these activities are used as part of the systems approach and how this relates in detail to elements of systems engineering (SE).

Stakeholder Responsibilities

The general principles of life cycle application discussed above apply as necessary to each application of SE. The following sections clarify the different kinds of stakeholder and the roles they take for the different system contexts discussed in the SEBoK.

Products, Services, and Enterprises

Most often, the terms "product" and "service" describe the effects that are exchanged in a customer and supplier agreement. This may be a commercial agreement, one funded publicly by a charity, or provided by a government agency. The difference between a product and a service is that a product is an artifact acquired to achieve an outcome while a service is an outcome supplied directly to a user.

The terms “customer” and “user” are often used interchangeably in engineering and management disciplines. The INCOSE *Systems Engineering Handbook* (INCOSE 2012) makes the following specific distinctions among the stakeholders associated with a system:

- The acquirer is the stakeholder that acquires or procures a product or service from a supplier.
- The supplier is an organization or individual that enters into an agreement with the acquirer to supply a product or service.
- The operator is an individual or organization that uses knowledge, skills and procedures to perform the functions of the system to provide the product or service.
- The user or customer is the individual or group that benefit from the operation of the system.

These terms define the roles stakeholders take; however, they may not always lie within these distinct entities (e.g. the acquirer may also be the user). This also applies to service systems, as some of the entities may also overlap in roles. Parnell et al. (2011) offer an alternative list of stakeholders that include decision authority, client, owner, user, consumer, and interconnected.

Product systems consist of hardware, software, and humans, and they have traditionally been the focus of SE efforts. These systems are delivered to the acquirer and operated to accomplish the goals that led to the requirements for the system. These requirements were derived from the need to provide products and services to one or more users as part of an enterprise.

The delivery (supplying) of a service is indicative of the direct delivery of an outcome, which is often related to the delivery of products (e.g., a maintenance, training, or cleaning service). This is not the same as the delivery of a service system (see the discussion below).

In traditional SE, the term “service” or “service system” refers to the wider system context that describes the acquirer's need to deliver user value. In this case, the service system is a fixed system definition that dictates the manner in which the acquiring enterprise will utilize the products to enable the delivery of services to users. Product systems are designed to be integrated and operated as appropriate to enable this service to be maintained or improved as required. In this view, a service system is static and contains dedicated products, people, and resources; that is, hierarchies of products are engineered to provide acquirers with the ability to offer predefined services to users or customers.

More recently, the term "service systems" has been used to describe a system that is engineered in a manner that allows enterprises to offer services directly to users, bypassing the need to hold all of the necessary products and services within the enterprise itself. This requires the expansion of the definition of a “supplier” as follows:

- A **product supplier** is an organization or individual that enters into an agreement with an acquirer to supply a product or related product support services.
- A **service system supplier** is an organization or individual that enters into an agreement with an acquirer to supply a service system.
- A **service supplier** is an organization or individual that enters into an agreement with a user to supply a service.

These service systems tend to be configured dynamically to deal with problems that traditional static services find challenging to address. This view of a service system employs "late binding" with product systems that are not owned by the enterprise but are used to enable the service to be offered as closely to given time demands as possible. This is the definition of a service system used in the Service Systems Engineering topic in Part 4, Applications of Systems Engineering.

Stakeholder Needs

One of the most critical stakeholder responsibilities is to identify the needs and requirements for the system that provides the products or services (INCOSE 2012). These needs and requirements are expressed in agreements between acquirers and suppliers.

There are other stakeholders who shape system requirements based on their needs, but who are not necessarily acquirers or suppliers. The stakeholders and the requirements engineers share the responsibility to identify their needs during the requirements process.

Acquirer/Supplier Agreements

Lawson (2010) provides a perspective on what it means to own systems, trade in system products and services, and the implications of supply chains in respect to the value added and ownership of the systems, its products and services. INCOSE (2012) defines two life cycle processes related to acquisition and supply. The acquisition process includes activities to identify, select, and reach commercial agreements with a product or service supplier.

In many larger organizations, there is a tradition of system ownership vested in individuals or, in some cases, enterprise entities (groups or teams). Ownership implies the authority and responsibility to create, manage, and dispose of a system-of-interest (SoI), as well as sometimes to operate the SoI.

Product Acquire/Supply

In some industries, a supplier works directly with an acquirer to help understand the acquirer's needs and then engineer one or more products to satisfy those needs. In certain cases, a single supplier will provide the complete worthy product system. In other cases, a supply chain will be formed to deliver product systems with a system integrator to ensure they fit together and integrate into the wider context. This is a theoretical view of product systems engineering in which the context is fixed and the product is designed to fit into it. A good systems engineer may suggest changes to the enterprise as a better way to solve the problem and then modify the product system's requirements accordingly. However, at some point, an agreed context will be set and a product system developed to work within it.

For many commercial products, such as mobile phones, a supplier creates a representative user profile to generate the requirement and then markets the product to real users once it is realized. In these cases, the other elements of the systems approach are performed by the acquirer/user and may not follow formal SE processes. It is important that a product supplier takes this into account when considering the best manner in which to engineer a system, as additional help or support services may need to be offered with the purchased product. The idea of a supplier offering support services for users with a type of product purchased elsewhere (e.g., an auto-mechanic servicing different makes of cars) begins to overlap with the service systems context, as discussed in the next topic.

For an institutionalized infrastructure in which SoIs are entirely owned by an enterprise or parties thereof, the entire responsibility of life cycle management, including operation, is often vested with the system owners. These systems belong to the system asset portfolio of an enterprise or multiple enterprises and provide the system resources, including the planned systems that are developed during life cycle management.

Service Acquire/Supply

Organizations providing service systems need not own the individual products and services that they deliver to their users and customers. With this viewpoint, the supplied service system includes the means to identify and gain access to appropriate products or services when needed. The service systems would then be the bundle of products and services assembled for the user; for example, assembling software applications and service agreements for a mobile phone already owned by a user. The enterprises providing service systems may, in turn, offer infrastructure services to a wide range of different technologies or application domains. This can mean that the transition, operation, maintenance and disposal activities associated with system ownership may not be embedded in the acquiring service system enterprise, and will therefore need to be treated as separate system services. More detail can be found in Product Systems Engineering, Service Systems Engineering, and Enterprise Systems Engineering, in Part 4, Applications of Systems Engineering in the *Guide to the Systems Engineering Body of Knowledge* (SEBoK).

The service systems engineer helps the service supplier create and sustain the service system that can be used to discover, integrate, and use specific versions of generic products or services when needed. The realization of service systems requires the ability to make use of product systems; however, these product systems are developed and owned outside of the service system. The service system must be able to gain access to a product or service when needed, as well as to interface with it effectively. The use of open interface standards, such as standard power supplies, interface connections (e.g., Universal Serial Bus (USB)), or file formats (e.g., Portable Document Format (PDF)) can help make this easier.

Enterprise Evolution

A useful distinction between product system design and enterprise system design is that “enterprise design does not occur at a single point in time like the design of most systems. Instead, enterprises evolve over time and are constantly changing, or are constantly being designed” (Giachetti 2010, xiii).

The enterprise developer may also aim to optimize backstage processes (the internal operations) of an organization or an institution by exploiting advances in technology, particularly information technology (IT) and associated processes. In these cases, the engineered systems are considered to be enterprise systems.

Enterprise systems may offer products (goods) and/or services. From an enterprise engineering viewpoint, an enterprise concurrent with its product SE must not only look at the development and delivery of the products but also look at the alignment and optimization of the product delivery within the enterprise objectives. Similarly, in service SE, the main focus is on an intangible value delivery to the end-customer (externally focused: front stage), in which internal and external processes must be synchronized. However, with the rapid advances in information and communications technologies (ICT), in many cases the boundaries between internal and external processes are quite blurred. Current SE research is extending product methods, processes, and tools into the enterprise transformation and service innovation fields to exploit advances in business process methodologies and technologies.

Enterprise SE must not only do the engineering of the enterprise itself but may also be involved in the engineering of the service systems and product systems that are necessary for the enterprise to achieve its goals.

Activity Mapping

This topic belongs to the Systems Approach Applied to Engineered Systems KA from Part 2, Foundations of Systems Engineering. Other topics about activities, from the same KA, relate to high level technical processes defined in KAs in Part 3, Systems Engineering and Management, in the following way:

- Identifying and Understanding Problems and Opportunities topic relates to the System Concept Definition KA.
- Synthesizing Possible Solutions and Analysis and Selection between Alternative Solutions topics relate to the System Definition KA.
- Implementing and Proving a Solution topic relates to the System Realization KA.
- Deploying, Using, and Sustaining Systems to Solve Problems topic relates to the Product and Service Life Management KA.

Part 3 discusses the principles defined in each of the systems approach activities, and how they help shape the technical processes to which they are mapped.

Systems Engineering and Management (SE&M) articles provide system lifecycle good practices for defining and executing interdisciplinary processes to ensure that customer needs are satisfied with a technical performance, schedule, and cost compliant solution. The figure below depicts the context of SE&M processes and practices guidance within the SEBoK.

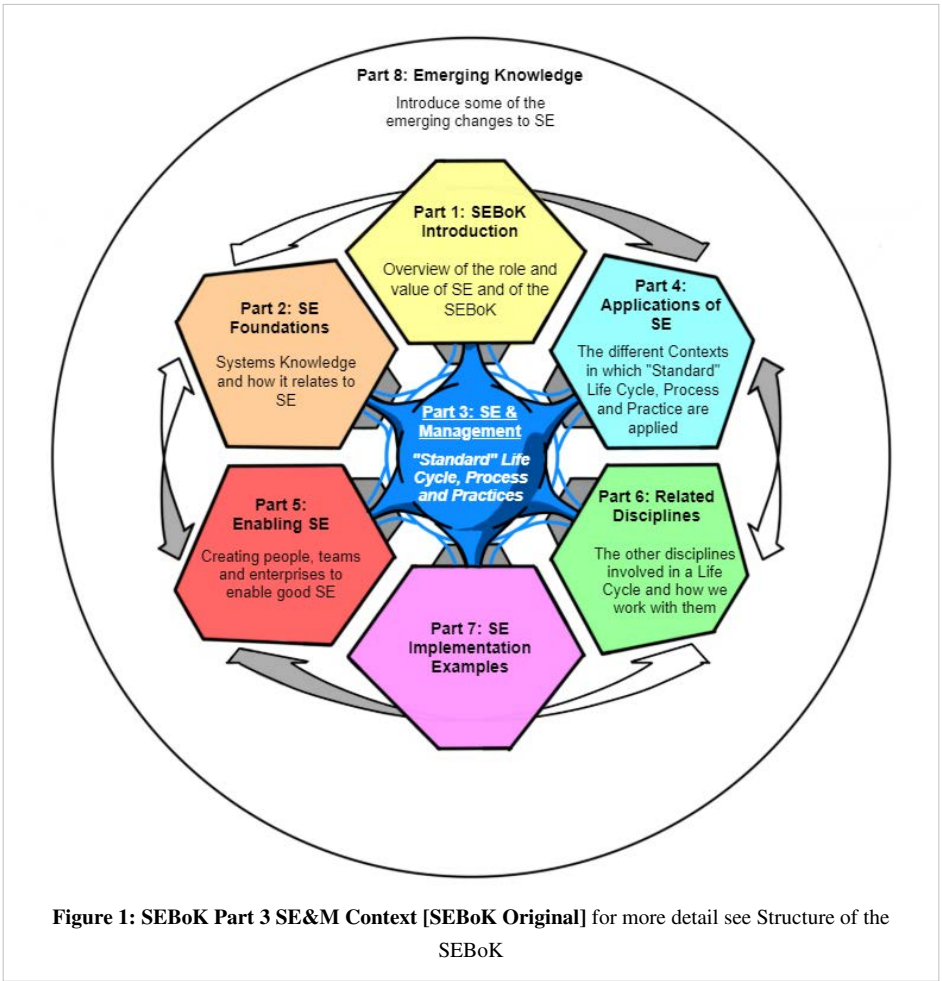

Figure 1: SEBoK Part 3 SE&M Context [SEBoK Original] for more detail see Structure of the SEBoK

The SE&M materials are currently being updated to better align with international standards.

SE&M Knowledge Areas

The SE&M articles are organized into the following Knowledge Areas [KAs].

- Life Cycle Terms and Concepts
- Development Approaches
- Agile Systems Engineering
- Life Cycle Model Selection and Adaptation
- Technical Management Processes
- System Concept Definition
- System Architecture Design Definition
- System Maintenance
- Systems Engineering Standards

The SE&M articles provide exemplary processes and practices which can be adapted by an engineering organization to satisfy strategic business goals and individual project objectives including:

- How engineering conducts system development
- The purpose of each engineering artifact generated
- How systems are integrated, and requirements verified
- How new product designs are transitioned to production operations
- How the resulting system is employed and sustained to satisfy customer needs

Part 3A - Life Cycle Concepts

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. There are various approaches to properly manage the progression of the system of interest through its life cycle stages as well as the planning for the other stages. In general, the approaches can be roughly divided into sequential, incremental and evolutionary approaches. Agile systems engineering is a principle-based method for designing, building, sustaining, and evolving systems when knowledge is uncertain and/or environments are dynamic. Life cycle models serve as essential frameworks that guide the development and management of systems and services throughout their existence. Tailored to organizational needs, these models help align projects with strategic goals while accommodating industry regulations and internal diversity. Life cycle models and development approaches can be selected and adapted to meet specific needs.

Knowledge Areas

The Part 3A - Life Cycle Concepts articles are organized into the following Knowledge Areas [KAs]:

- Knowledge Area – Life Cycle Terms and Concepts
- Knowledge Area – Development Approaches
- Knowledge Area – Agile Systems Engineering
- Knowledge Area – Life Cycle Model Selection and Adaptation

Systems Engineering STEM Overview

Engineering disciplines (ME, EE, CE, ChE) sometimes argue their fields have “real physical phenomena”, “hard science” based laws, and first principles, claiming Systems Engineering lacks equivalent phenomenological foundation. Here we argue the opposite, and how replanting systems engineering in MBSE/PBSE supports emergence of new hard sciences and phenomena-based domain disciplines with deep historical roots. Supporting this perspective is the System Phenomenon, wellspring of engineering opportunities and challenges. Governed by Hamilton’s Principle, it is a traditional path for derivation of equations of motion or physical laws of so-called “fundamental” physical phenomena of mechanics, electromagnetics, chemistry, and thermodynamics.

We argue that laws and phenomena of traditional disciplines are less fundamental than the System Phenomenon from which they spring—an historical fact that was well-known and equally remarkable 200 years earlier to the pioneers of mathematical physics. This is a practical reminder of emerging higher disciplines, with their own phenomena, first principles, and physical laws. Contemporary examples include ground vehicles, aircraft, marine vessels, and biochemical networks; ahead are health care, distribution networks, market systems, ecologies, and the IoT.

Introduction

As a formal body of knowledge and practice, Systems Engineering is much younger than the more established engineering disciplines, such as Civil, Mechanical, Chemical, and Electrical Engineering. Comparing their underlying scientific foundations to some equivalent in Systems Engineering sometimes arises as a dispute, concerning whose profession is “real” engineering based on (or at least later explained by) hard science, with tangible physical phenomena, and accompanied by physical laws and first principles. This paper summarizes the argument for a different perspective altogether (Figure 1), and the reader exploring this paper is warned to avoid the trap of the

seemingly familiar in parsing the message. A more complete discussion is provided in (Schindel 2016) and (Schindel 2019).

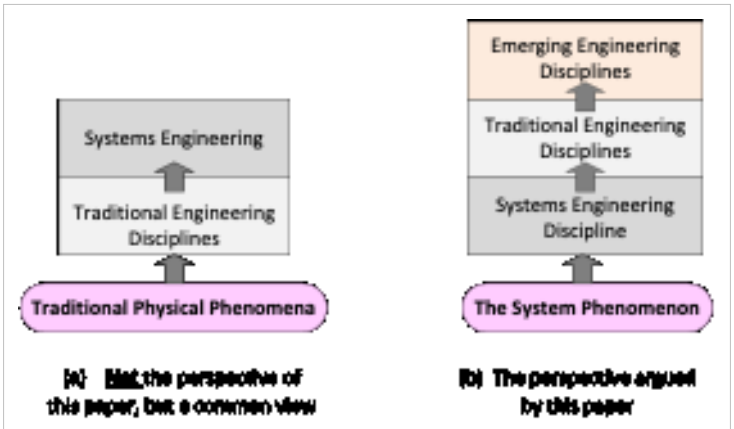

Figure 1: Two Different Views of Systems Engineering. (SEBoK Original)

Beyond that argument, this paper addresses a more pragmatic goal—the means of identifying and representing the tangible physical phenomena that emerge in new system domains, along with their respective physical laws and first principles. This is of more than philosophical or professional significance. Challenged by numerous issues in emerging systems, society has an interest in organizing successful approaches to the scientific understanding of laws and first principles about, and engineering harnessing of, the related phenomena. Individuals entering or navigating the technical professions likewise have personal interests in this evolving roadmap.

While recognizing the formidable works of systems theorists in these still early days of systems engineering (Ashby 1956; Bertalanffy 1969; Braha et al 2006; Cowan et al 1994; Holland 1998; Prigogine 1980; Warfield 2006; Wymore 1967), this paper focuses on even earlier contributions of science and mathematics to the flowering of engineering's impact over the last three centuries. We will extract the "System Phenomenon" at the center of that foundation and consider its impacts and implications for systems engineering practice. This perspective helps us understand the phase change that Systems Engineering is going through, as model-based representations enable the framework that has already had profound impact in the traditional science/engineering paired disciplines.

Phase Change Evidence: Efficacy of Hard Science, Phenomena-Based, STEM Disciplines

Science, Technology, Engineering, and Mathematics [STEM] —300 Years of Impact

Our pragmatic argument is based on assessing the impact of the physical sciences and mathematics on engineering by their joint efficacy in improving the human condition. In a matter of 300 years (from around Newton), the accelerating emergence of Science, Technology, Engineering, and Mathematics (STEM) has lifted the possibility, quality, and length of life for a large portion of humanity, while dramatically increasing human future potential (Mokyr 2009; Morris 2012; Rogers 2003). By the close of the Twentieth Century, the learning and impacts of STEM along with other factors (e.g., market capitalism as a driver of prosperity, as in (Friedman 1980)) were increasingly recognized as critical to individual and collective human prosperity. During that same period, the human-populated world has become vastly more interconnected, complex, and challenging. New opportunities and threats have emerged, in part out of less positive impacts of human applications of STEM. Understanding and harnessing the possibilities have become even more important than before, from the smallest known constituents of matter and life to the largest scale complexities of networks, economies, the natural environment, and living systems

"Phase Changes": Emergence of Science and Engineering as Phenomena-Based Disciplines

Over those three centuries, the "hard sciences", along with the engineering disciplines and technologies based on those sciences, are credited with much of this amazing societal progress, as well as some related challenges (Mokyr 2009; Morris 2012; Rogers 2003). Our point here is the enormous impact of these "traditional" (at least, over 300 short years) disciplines, as their foundations emerged in understanding of physical phenomena and related predictive and explanatory models.

How can the foundational roots of Systems Engineering be compared to engineering disciplines already seen as based on the "hard sciences"? The traditional engineering disciplines (ME, EE, ChE, CE) have their technical bases and quantitative foundations in what emerged as physical sciences of what came to be understood as physical phenomena.

It wasn't always this way, as seen from the shift that began to occur just three centuries ago. It is informative to remember the "phase changes" that occurred in what are now considered the traditional disciplines, by recalling the history of physics before Newton, chemistry before Lavoisier and Mendeleev, and electrical science before Faraday, Hertz, and Maxwell, versus what followed for each. (Cardwell 1971; Forbes et al 2014; Pauling 1960; Servos 1996; Westfall 1980) All of these domains had earlier, less effective, bodies of thought, generated by those attempting to answer questions and, in some cases, provide practical benefits. Instead of dismissing alchemy, astrology, pre-Copernican cosmology, and their counterparts, we can instead see them as grappling with phenomena without the benefit of sufficiently powerful physical-mathematical representation and the verification mechanisms of experiment and refutation to test against reality what we would now call models.

Systems Engineering is Still Young

Contemporary specialists in individual engineering disciplines (e.g., ME, EE, CE, ChE) sometimes argue that their fields are based on "real physical phenomena", founded on physical laws based in the "hard sciences" and first principles. One sometimes hears claims that Systems Engineering lacks the equivalent phenomena-based theoretical foundations. In that telling, Systems Engineering is instead critically portrayed as emphasizing (1) process and procedure, (2) critical and systems thinking and good writing skills, and (3) organizing and accounting for information and risk in particular ways—valuable, but not as based on an underlying "hard science".

That view is understandable, given the initial trajectory of the first 50 years of Systems Engineering. (Adcock 2015; Checkland 1981; Walden et al 2015) "Science" or "phenomenon" of generalized systems have for the most part been described on an intuitive or qualitative basis, with limited reference to a "physical phenomenon" that might be called the basis of systems science and systems engineering. Some systemic phenomena (e.g., requisite variety, emergence of structure, complexity, chaos theory, etc.) have received attention, but it is challenging to argue that these insights have had as great an impact (yet) on the human condition and engineering practice as the broader STEM illustrations cited above for the most recent three centuries of physical sciences and mathematics. However, INCOSE's own stated vision (Friedenthal et al 2014) calls upon systems engineering for such a result.

Respectful of the contributions of those early thinkers in systems engineering, we also note that their contributions can in some cases be expressed as manifestations of the modeled System Phenomenon described below, advancing the scientific foundations of systems engineering.

MBSE, PBSE: Enabling a Phase Change in Systems Engineering

In the case of systems engineering, a key part of the story is that the role that quantitative system models have played, or not played, during its initial history. Most recently, the broader INCOSE-encouraged role for model-based methods offers to eventually accelerate the "phase change" that the successful earlier history of science, mathematics, and other engineering disciplines suggest is now in progress.

Models are certainly not new to segments of engineering practice. However, we are representing an increasingly fraction of our overall understanding of systems, from stakeholder trade space, to required functionality and performance, to design, and to risk, using explicit and increasingly integrated system models. As in Newton's day, this also puts pressure on the approaches to model representations, in order that they effectively represent the key ideas concerning the real things they are intended to describe. "Effective" meant these models described observable phenomena, offered explanatory theories of cause, provided verifiable (or falsifiable) predictions, and increased human understanding. In many cases, this understanding was harnessed by practicing engineers to improve human life. The progress of physical sciences did not arise from models that only could describe single unique instances of systems, but instead represented what came to be understood as more general patterns that recur across broad families of systems. Likewise, there is an increasing effort in systems engineering to recognize that these models must often describe patterns of similarity and parameterized variation. The increasing use of explicit model-based patterns in these representations is a part of this phase change (INCOSE Patterns WG 2015; INCOSE MBSE Initiative 2015). Pattern-Based Systems Engineering (PBSE) as an extension of Model-Based Systems Engineering (MBSE) increases emphasis on representation.

This is a more significant change than just the emergence of standards for systems modeling languages and IT toolsets, even though those are valuable steps. We need underlying model structures that are strong enough--remember physics before the calculus of Newton & Leibniz. As a test of "strong enough", we suggest the ability to have the kinds of impact on humankind summarized in Section 2—beginning with clearer focus on what phenomena are being represented.

Although this sounds challenging, it is not necessary for emerging systems models to "start from scratch" in their search for new system phenomena, and further argue that what is already known from the earlier phase change of Section 2 helps suggest what aspects of our systems models need to be strengthened during the phase change in systems engineering. PBSE further reminds us of a practical lesson from the STEM revolution. Once validated patterns emerge, we (mostly) need to learn and apply those patterns (laws, principles), not how to re-derive them from earlier knowledge. Examples include the Periodic Table and the Gas Laws. While it may be controversial, "learn the model, not modeling" is advice worth considering, in a time when modeling from scratch seems carry more excitement.

The System Phenomenon

The perspective used in this paper defines a system as a collecting of interacting components, where interactions involve the exchange of energy, force, mass, or information, through which one component impacts the state of another component, and in which the state of a component impacts its behaviour in future interactions (Schindel 2011).

In this framework, all behaviour is expressed through physical interactions (Figure 2). This perspective emphasizes physical interactions as the context in which all the laws of the hard sciences are expressed. (Schindel 2013)

Figure 2: The System Perspective. (SEBoK Original)

The traditional "Phenomena" of the hard sciences are all cases of the following System Phenomenon:

1. Each component has a specific behavior during a given interaction type, determined by the component's state. (See (4) below for the source of that component's behavioral characteristics.)
2. The combined behaviors of the set of interacting components determine a combined system state space trajectory.
3. That trajectory is a collective property of the system components and interaction, and accordingly is not simply the description of possible behaviors of the individual components. For the systems discussed in this paper, by Hamilton's Principle (Levi 2014; Sussman et al 2001; Hankins 2004), the emergent interaction-based behavior of the larger system is a "stationary" trajectory X = X(t) of the action integral, based on the Lagrangian L of the combined system:

$$S[X] = \int_A^B L(X, \dot{X}, t)dt$$

1. The behavioural characteristics of each interacting component in (1) above are in turn determined by its internal ("subsystem") components, themselves interacting.

Reduced to simplest forms, the resulting equations of motion (or if not known or solvable, empirically observed paths) provide "physical laws" (or recurring observable behaviors) subject to verification.

Instead of Systems Engineering lacking the kind of theoretical foundation that the "hard sciences" bring to other engineering disciplines, we therefore assert that:

- It turns out that all those other engineering disciplines' foundations are themselves dependent upon the System Phenomenon, and emerge from it.
- The related underlying math and science of systems (dating to at least Hamilton) provides the theoretical basis already used by all the hard sciences and their respective engineering disciplines.
- It is not Systems Engineering that lacks its own foundation—instead, it has been providing the foundation for the other disciplines! (Refer to Figure 6.)
- This insight was well-known and remarkable to the sciences 200 years ago, and has continued to be remarked upon by leading scientists for its surprising coverage ever since: "It [science] has as its highest principle and most coveted aim the solution of the problem to condense all natural phenomena which have been observed and are still to be observed into one simple principle, that allows the computation of past and more especially of future processes from present ones. ...Amid the more or less general laws which mark the achievements of physical science during the course of the last centuries, the principle of least action is perhaps that which, as regards form and content, may claim to come nearest to that ideal final aim of theoretical research." (Kline, 1981)

Historical Domain Example 1: Chemistry

Chemists, and Chemical Engineers, justifiably consider their disciplines to be based on the "hard phenomena" of Chemistry (Pauling 1960; Servos 1996):

- This perspective emerged from the scientific discovery and verification of phenomena and laws of Chemistry.
- Prominent among these was the discovery of the individual Chemical Elements and their Chemical Properties, organized by the discovered patterns of the Periodic Table.
- Emerging understanding of related phenomena and behaviors included Chemical Bonds, Chemical Reactions, Reaction Rates, Chemical Energy, and Conservation of Mass and Energy.
- Upon that structure grew further understanding of Chemical Compounds and their Properties:

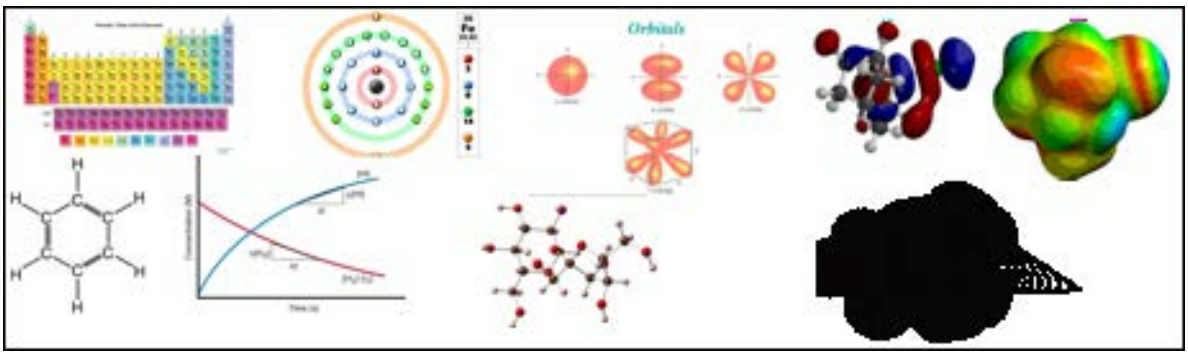

Figure 3: Chemical Interactions, Phenomena, Principles. (SEBoK Original

Even though these chemical phenomena and laws seemed very fundamental:

- All those chemical properties and behaviors are emergent consequences of interactions that occur between atoms' orbiting electrons (or their quantum equivalents), along with limited properties (e.g., atomic weights) of the rest of the atoms they orbit.
- These lower interactions give rise to visible higher-level Chemical behaviour patterns, their own higher-level properties and relationships, expressing "hard science" laws of Chemistry.

This illustrates:

- The "fundamental phenomena" of Chemistry, along with the scientifically-discovered / verified "fundamental laws / first principles" are in fact . . .
- Higher level emergent system patterns and . . .
- Chemistry and Chemical Engineering study and apply those system patterns.

Historical Domain Example 2: The Gas Laws and Fluid Flow

Illustrated by Figure 4, the discovered and verified laws of gases and of compressible and incompressible fluid flow by Boyle, Avogadro, Charles, Gay-Lussac, Bernoulli, and others are rightly viewed as fundamental to science and engineering disciplines. (Cardwell 1971) However, all those fluid and gaseous properties and behaviors are emergent consequences of interactions that occur between atoms or molecules, the containers they occupy, and their external thermal environment. These lower-level interactions give rise to patterns that have their own higher-level properties and relationships, expressed as "hard sciences" laws. So, the "fundamental phenomena" of gases, along with the scientifically-discovered and verified "fundamental laws and first principles" are in fact higher level emergent system patterns. And so, Mechanical Engineers, Thermodynamicists, and Aerospace Engineers can study and apply those system patterns.

[[File: |thumb|center|750px|*Figure 4: Gas, Fluid Interactions, Phenomena, Principles.* (SEBoK Original)]]

Examples from More Recent History

The practical point of this paper is to emphasize the constant emergence of new scientific and engineering disciplines, in domains arising from higher level system interactions. These include domains that have been important to society, even though they arose later than the more fundamental domains from which they spring. The discovery and exploitation of these higher-level phenomena, principles, and laws is important to future progress and innovation, including enterprises, careers of individuals, and society. These more recent emergent domains, in which formal system patterns are being recognized as describing higher-level phenomena and laws, are illustrated by examples of Figure 8:

1. Ground Vehicles: As in the dynamical laws of vehicle stability that enable vehicular stability controls (Guiggiani 2014)
2. Aircraft: Including the dynamical laws at the aircraft level that enable advanced aircraft design for dynamic performance and top-level flight controls (Pratt 2000)
3. Marine Vessels: Facilitating the design of more efficient hulls and special purpose craft, as well as bulk transports (Perez et al 2007)
4. Biological Regulatory Networks: Advancing our understanding of immune reactions and other regulatory paths in connection with pathologies as well as therapies (Davidson and Levine 2005).

For example, in the case of ground vehicles, dynamical laws of vehicle stability arise from the interactions, modulated through control algorithms, of the distributed mass of the vehicle in motion with the driving surface, transmitted through tractional forces of braking, acceleration, or steering, as further impacted by road surface and tire conditions, along with other factors. It is the overall system interaction of all these domain elements that leads to emergent vehicular laws of motion.

Students of complexity (Cowan et al 1994) will note that nonlinearity, the onset of chaos, and extreme interdependencies are not reasons to avoid representing the interactions manifesting that behavior. Indeed, they provide further reasons to understand those very interactions.

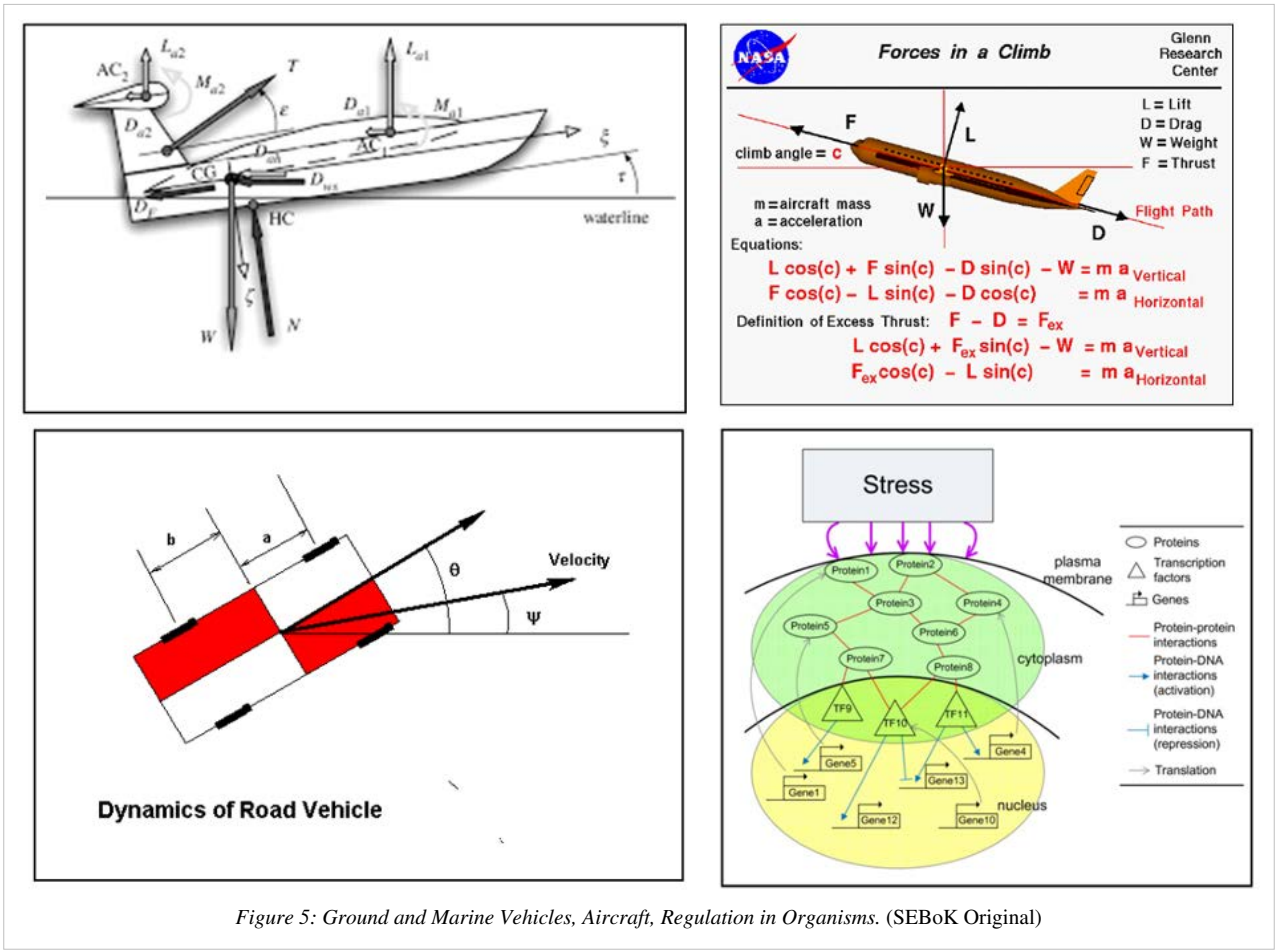

Figure 5: Ground and Marine Vehicles, Aircraft, Regulation in Organisms. (SEBoK Original)

Examples that call out for improved future efficacy in systems engineering include:

1. Utility and other distribution networks: Society depends upon rapidly evolving, often global, networks for distribution of goods and services, in the form of materials, energy, communication, and information services. What are the network-level phenomena, laws, and principles of these networks, bearing on their effectiveness and resiliency? (Perez-Arriaaga et al 2013)
2. Market systems, economies, and human-imposed regulatory frameworks: These systems clearly have direct impact on society and individuals. The “designed” systems of top-down regulation imposed upon them include such prominent examples as regulation of banking, securities markets, development of medical devices and compounds, and delivery of health care. What are the system-level phenomena, laws, and principles of these systems, bearing on their effectiveness and resiliency? (Friedman 1980)
3. Living ecologies: The emergent habitats of living things include rain forests, coral reefs, the human microbiome, and the biosphere as a whole. These demonstrate characteristics that include regulatory stability within limits, along with pathologies. What are the system-level phenomena, laws, and principles of these systems? (MacArthur & Wilson 2001)
4. Health care delivery: These systems, including a number of important challenges, are much in the public eye. The very definition of effective health care is necessarily dynamic because of the evolving frontiers of medical science. The means of effectively delivering care, financing its costs, and (Hippocratically) protecting patients from harm are all subject of study as to system-level phenomena and principles. (Holdren et al 2014)
5. Product development, general innovation, and related agility: This system domain is the “home court” of INCOSE and our systems engineering profession. While there is a large body of descriptions of the related systems, the study of these systems as modelled technical systems is mostly new or in the future. One such project is the INCOSE Agile Systems Engineering Life Cycle Model Project. (Braha et al 2007; Schindel and Dove 2016; Hoffman 2015)

Strengthening the Foundations of MBSE

Like mechanics pre-Newton, models of MBSE require an underlying framework to effectively describe the System Phenomenon in domains of practice. MBSE requires a strong enough underlying Metamodel to support phenomenon-based systems science. As discussed in (Schindel 2013), Interactions play a central role in such frameworks, inspired by Hamilton and three hundred years of pioneers in the emergence of science and engineering. Interactions are acknowledged by and can be modelled in some current system modelling frameworks, but typical practice and underlying structures need related improvement. Figure 9 illustrates a related, Interaction-centric, extract from the S*Metamodel (Schindel 2011).

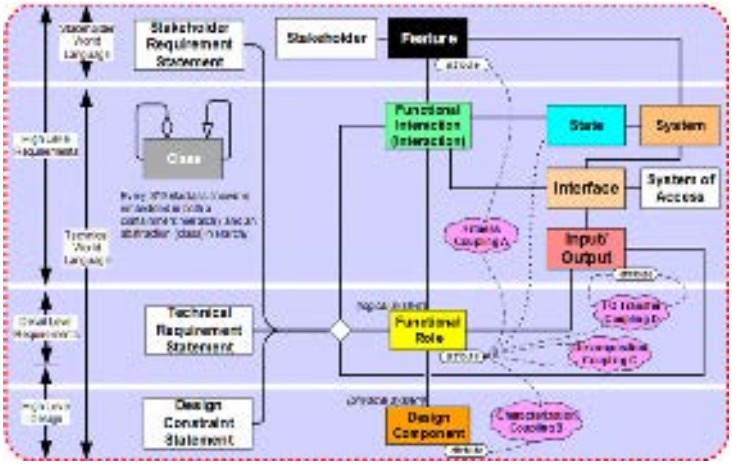

*Figure 6: Summary View of S*Metamodel.* (SEBoK Original)

This is more than model semantics or ontology alone. It means recognizing that the models we pursue are models of the real physical systems they are about, and not just models of information about business processes concerned with those systems. While that might seem obvious to the physical scientist, a different perspective than that is embedded in forty years of enterprise information system practice. In that history, the traditional (and relatively successful) paradigm is construction of information models that describe information transactions or documents (e.g., purchase of air travel tickets). Symptomatic of that paradigm, today we still encounter MBSE models and human interpretations of them that include notions of databases, “calls”, “methods”, and other successful software notions that are not the same as modeling physical systems.

Conclusions and Implications for Future Action

1. Like the other engineering disciplines, Systems Engineering can be viewed as founded on “real” physical phenomena—the System Phenomenon—for which experimentally verified, mathematically modeled hard science, laws, and first principles have existed for over 150 years, dating to Hamilton, or earlier, to Newton.
2. Systems Engineering not only has its own phenomenon, but the phenomena upon which the traditional engineering disciplines (ME, CE, ChE, EE) are based can themselves all be seen to be derivable from the System Phenomenon. It is SE that has the more fundamental foundation, while the other disciplines are special cases of both the phenomena and mathematics.
3. The System Phenomenon supports the emergence of hard sciences, laws, and first principles for higher level phenomena of critical importance to humankind.
4. Systems Engineering, along with its related scientific foundations, is a young and still emerging discipline. The re-planting of Systems Engineering in a model-based framework is an important step toward strengthening the discipline, but requires a stronger model framework for that to occur, and the System Phenomenon points the way to a key part of that framework.

5. A practical implication for practicing systems engineers and their educators: All models of behavior should be based on interactions. Nature offers no “naked” behavior outside interactions, but current practice and training often seem to overlook this.
6. Systems research emphasis would benefit from more attention to specific emergent domains, each of which will have their own phenomena, instead of over-emphasizing abstract generic systems. This is a well-described but often overlooked observation, as noted in (Anderson 1972)
7. There are additional phenomena in this space. For a discussion of the Value Selection Phenomenon and Group Learning and Model Trust Phenomenon, see (Schindel 2020).

Model-Based Systems Engineering (MBSE)

- Lead Authors:
- Caitlyn Singam and Jeffrey Carter

-

Model-based Systems Engineering [MBSE] is a paradigm that uses formalized representations of systems, known as models, to support and facilitate the performance of Systems Engineering [SE] tasks throughout a system's life cycle. MBSE is frequently contrasted with legacy document-based approaches where systems engineering captures system design information via multiple independent documents in various non-standardized formats. MBSE consolidates of system information in system design models, which provide primary SE artifacts. These system models, which are generally expressed in a standardized modelling language such as Systems Modeling Language [SysML®] express key system information in a concise, consistent, correct, and coherent format. When implemented properly, MBSE models permit the standardized consolidation and integration of system knowledge across engineering disciplines and subsystems and streamline key systems engineering tasks while also minimizing developmental risk.

This article provides an overview of key concepts underlying model-based approaches to systems engineering and highlights the benefits of utilizing MBSE on projects.

System Models

During the systems engineering process, a substantial amount of information is collected, generated, and/or maintained regarding the characteristics of the system(s) of interest, composite elements, and interacting entities/environments. MBSE utilizes models as a means of aggregating and managing these disparate pieces of information about a system in a centralized repository that can serve as a 'single source of truth' and technical baseline regarding a system of interest.

Definitions

Models are representations that are used to capture, analyze, and/or communicate information about a system or concept. They can vary in scope, purpose, and type, and can be utilized both individually as stand-alone entities as well as in concert with each other as part of an integrated set (Wymore 1993).

Properties of System Models

A model can be described and classified with respect to the following properties:

- Scope: the range of relevance of a model. Models can range from capturing the characteristics and interactions of a system's components (broad scope), to only focusing on the form and function of a single element in isolation (narrow scope).
- Domain: the 'lens' through which the model views a system. Models can be holistic in nature or can focus on only highlighting information relevant to certain domains. Domain-specific models generally are used to highlight certain "perspectives" of a system, whether from the lens of a particular application sector (e.g., aerospace, biomedicine), discipline (e.g., electrical, mechanical, thermal), subsystem, or system property (e.g., power, reliability, fault management).
- Formality: the model's level of adherence to formalized standards for information expression. Models can express information about systems with varying degrees of precision. The most fundamental of models, which simply express a basic representation of a system in an unspecified format, do not convey information with precision and are considered informal. The most formal models comply with well-developed, pre-defined standards (formalisms) for content and organization, which collectively define 'languages' that enable consistent and precise interpretations of models.
- Abstraction: the degree to which a model suppresses or excludes out-of-scope, unimportant, or irrelevant details. Abstraction is a necessity with large and complex systems where it is impractical to replicate every aspect of a given system within a reasonable time and resource expenditure margin.
- Physical/conceptual: whether the model is concrete in nature (i.e., a physical model) or fully conceptual (i.e., an abstract model).
- Descriptive/analytical: whether a model details qualitative aspects of a system such as requirements, behaviors, or physical architecture (descriptive model), provides a representation of quantitative aspects of the system such as mass, reliability, power consumption via mathematical relationships (analytical model), or both (hybrid model).
- Fidelity: the degree to which a model comprehensively captures details about a system's characteristics, ranging from models which only capture general information about a system to those which seek to faithfully capture as much detail about the system as possible.
- Completeness: the extent to which a model captures all relevant domain- information within its scope and at its intended level of detail.
- Integration: the extent to which a model interacts and interfaces with other relevant models describing the system of interest or other related/interacting entities.
- Quality: the degree to which the model (not the system it represents) meets the needs of the individuals performing systems engineering activities. A high-quality model should be readily usable, have minimal ambiguity, and provide accurate, relevant information needed to support tasks associated with the design, development, operation, and/or maintenance of a system.

Of these properties, formalization and abstraction are generally the most frequently discussed in relation to MBSE (Vogelsang et al. 2017) as they have the greatest impact on whether a model can be effectively used as part of an MBSE workflow.

Criteria for Effective MBSE Models

While a successful MBSE workflow can involve the use of several different interconnected or standalone models of various scopes and types based on user needs, the main system model in an MBSE projects generally should have the following characteristics:

1. A scope which matches the scope of the project (i.e., it should encompass the entire system of interest);
2. Representative of a holistic perspective from all relevant domains.
3. Strict compliance with a previously established standardized modeling language, whether that be an existing language such as SysML® or a custom formalism.
4. Fully abstracted, to only include relevant information appropriate for the system of interest and its desired use-case(s).
5. Conceptual in nature, to permit the capture of intangible information (e.g., system requirements)
6. Containing a description of the system functional and structural architecture at minimum and supplemented by integrated analytical/quantitative property descriptions as needed.
7. Demonstrating sufficient fidelity to capture relevant system elements and behavior.
8. Fully complete given its scope.
9. Integrated with any necessary auxiliary models.
10. Sufficiently high-quality as to meet the needs of those designing, developing, or otherwise working on the system.

In terms of content, effective system models are expected to capture key system information regarding requirements, system functionality/behavior, structure/form, properties, and interconnections between system components.

Modeling Languages

Modeling languages are specifications which provide standardized guidelines and structures for expressing system information. These languages, which provide both the structures or 'syntax' in which the information can be expressed, as well as the 'semantics' that govern the way in which the information should be interpreted, can be selected based on user preferences and needs. Different languages utilize different formats to express information (e.g., visual or textual means), as well as different paradigms (e.g., object-oriented, functional, etc.) in order to group information. Visual languages are generally preferred for modeling due to being readily readable, and object-oriented modeling languages are frequently used in systems engineering contexts since they readily lend themselves to systems which can be decomposed, or otherwise thought of, in terms of objects.

SysML®, an extension of Unified Modeling Language [UML] for systems engineering, is a one of the more frequently used modeling languages for MBSE. It is an graphical language that utilizes diagrams and tables in order to express system information, and provides a standard set of nine diagram types which can be used to organize and express system information (Friedenthal, Moore, and Steiner 2014). The collective diagrams (each of which can be considered a model in its own right), when interconnected, provide a means of representing system structure, behavior, and requirements in abstracted form. A number of other options have been proposed as architecture description languages [ADLs] for specifically modeling system architectures. ISO/IEC/IEEE 42010 (Systems and software engineering - Architecture description) specifies minimum requirements for a language to qualify as an ADL (ISO 2011).

MBSE users have the option of using SysML®, a similar graphical-language option like UML, a domain or framework specific language, or potentially developing a custom formalism for their team or organization (Bonnet et al. 2016). It is possible to formalize textual documents to create models, though doing so requires the establishment of a domain dictionary in order to remove the ambiguity inherent in diction choice, as well as the use of rigid grammatical structures which may limit readability.

Regardless of what modeling language is used for an MBSE project, it is important that the language be inherently scalable, standardized, readable, reusable, and abstractable to enable the development of effective MBSE models.

Architecture Frameworks

A second layer of structure that exists overtop a modeling language is an architecture framework. Architecture frameworks are used to organize the information expressed via modeling language. Whereas a modeling language provides the structure needed to express multiple 'views' (diagrams) of system elements and their interactions, architecture frameworks enable the user to group those views based on the elements they represent, and organize them in a way that allows traceability, eases navigation through the model, and aids in the identification of missing information (e.g., an omitted element). Architecture frameworks are a specific type of pattern that frequently get defined and standardized for MBSE models. There are also organization- and domain-specific design patterns that can be employed in MBSE models to meet stakeholder needs in more specific model use-cases.

Architecture frameworks and model design patterns play an important role in enabling the re-use of MBSE models (Wu et al. 2019), as certain architectural design patterns may be frequently used across multiple projects even when the specifications of the individual components differ (e.g. building a house with the same structure but different décor). By organizing a system model in a sufficiently abstracted manner, it may be possible to identify the points of difference between an old project and a new one and make the appropriate changes to element properties in the model without having to redo the entire model development process.

Process Frameworks

The MBSE model development workflow can be streamlined using pre-defined process frameworks, which provide tailorable guidelines and patterns for integrating MBSE into the generic systems engineering process. While process frameworks are typically defined on an organizational level, they generally all exhibit some form of configuration management process, access guidelines, practices for updating the model, and means of integrating the MBSE model into all or nearly all systems engineering lifecycle activities. The benefits of MBSE usage are limited when the system model falls out of date or otherwise becomes inaccurate, so regular model updates are a minimum requirement for MBSE process frameworks.

For smaller projects, the MBSE process framework may be as simple as utilizing the version control features that come included as part of many collaborative modeling software platforms and integrating model usage and periodic updates as checkpoints in the systems engineering process. More complex projects can formalize MBSE process frameworks in a manner that can be verified against configuration management and systems engineering management plans (Fisher et al. 2014).

Benefits of MBSE

The MBSE workflow and the creation of a centralized system model emphasizes a holistic, standards-based approach to systems engineering (Madni and Sievers 2018). Since the creation of a system model requires reconciliation of information from multiple domains and subsystems, inconsistencies and defects are readily identifiable during the modeling process (Carroll and Malins 2016) and can be addressed or eliminated earlier on in the system lifecycle process than would otherwise be done in a document-based workflow. Similarly, the centralization and standardization of information ensures a reduction in miscommunications and other development risks since all project team members are using the same source of information for reference. Format standardization also makes it easier to search for and extract information, compared to a document-based workflow where information is stored across multiple documents in different formats.

More broadly, MBSE provides a better means of managing complexity than document-based using formalized structures and abstraction. Cross-referencing within MBSE models makes it possible to begin design verification,

requirements validation, and systems assurance earlier on in the system lifecycle, and to continue assessing system design quality throughout a project at minimum cost. Furthermore, models can be reused and adapted for similar systems, which enables accelerated system development with minimal risk.

Digital Transformation

While DBSE has traditionally been the paradigm of preference for artifact generation and for supporting systems engineering efforts in the pre-digital age, digital transformation of the generic systems engineering workflow in recent years has catalyzed the widespread adoption of MBSE and broader model-based [MBx] approaches. Digital environments and software tools have made it easier and faster to generate, maintain, and use system models, especially in a collaborative setting (Ma et al. 2022). If implemented appropriately, digital MBSE models can be used to programmatically identify inconsistencies, enable interactive simulations of system behavior, simultaneously propagate changes across an entire project (rather than updating artifacts one-by-one), automatically generate document-based artifacts, and more. The advent of new software for supporting and automating systems engineering tasks has opened additional avenues for expanding the capabilities of system models, and for increasing the efficiency with which systems engineering tasks can be performed.

Digital Twins

When MBSE models of physical systems are built with sufficient completeness and fidelity, it is possible for them to function as 'digital twins' of the systems they represent. Digital twins provide a means of accurately representing a system's form and function throughout the system's lifecycle, all within a digital environment. Creating such digital twins provides number of advantages, including allowing individuals to perform testing, analysis, and optimization of systems in a virtual environment at no risk to the actual system of interest and often at a greatly reduced cost/burden (Schluse, Atorf, and Rossmann 2017). Digital twins also make it possible to represent the behavior of systems under conditions which would be impractical or impossible to induce under experimental conditions, thereby making it possible to obtain information not obtainable via study of the original physical system.

MBSE versus DBSE

Although MBSE and document-based approaches are usually presented as alternatives to each other, it is possible to use MBSE and document-based in conjunction with each other on the same project. In work environments where document-based is the norm, stakeholders may expect or require the submission of textual document artifacts, or there may be issues with a lack of familiarity with any modeling languages (Kim, Wagner, and Jimenez 2019); in such instances, it may be necessary to utilize a hybrid approach where documents are generated from the design model as static representations of the system for project milestones.

-

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. (ISO/IEC/IEEE 24748-1:2024) It can be helpful to create models to depict and manage the progression of the entity from beginning to end. These models are called life cycle models. A stage is a period within the life cycle of an entity that relates to the state of its description or realization. Stages relate to major progress, achievement milestones, or decision points of the entity through its life cycle. Technical reviews and audits are a mechanism by which sufficiently independent and knowledgeable stakeholders analyze the current state of a system, work product, or set of work products using pre-established criteria.

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. (ISO/IEC/IEEE 24748-1:2024) A stage is a period within the life cycle of an entity that relates to the state of its description or realization. Stages relate to major progress, achievement milestones, or decision points of the entity through its life cycle. It can be helpful to create models to depict and manage the progression from beginning to end. These models are called life cycle models.

Basic terms and concepts

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. (ISO/IEC/IEEE 24748-1:2024)

It can be helpful to create models to depict and manage the progression of an entity from beginning to end. These models are called life cycle models. A life cycle model is a framework of processes and activities concerned with the life cycle which can be organized into stages, acting as a common reference for communication and understanding (ISO/IEC/IEEE 24748-1:2024) See “Knowledge Area – Life Cycle Model Selection and Adaptation” for further elaboration.

A stage is a period within the life cycle of an entity that relates to the state of its description or realization. Stages relate to major progress, achievement milestones, or decision points of the entity through its life cycle. Stages often overlap. (ISO/IEC/IEEE 24748-1:2024) See “Article – Life Cycle Stages” for more information about stages, including entry and exit criteria for progressing between stages, and “Article – Technical Reviews and Audits” for assessing progress within stages.

Figure 1 shows a spectrum of life cycle approaches, depending on the level of uncertainty. All life cycle approaches fall somewhere between the two ends of the spectrum, with neither end of the spectrum being common in practice.

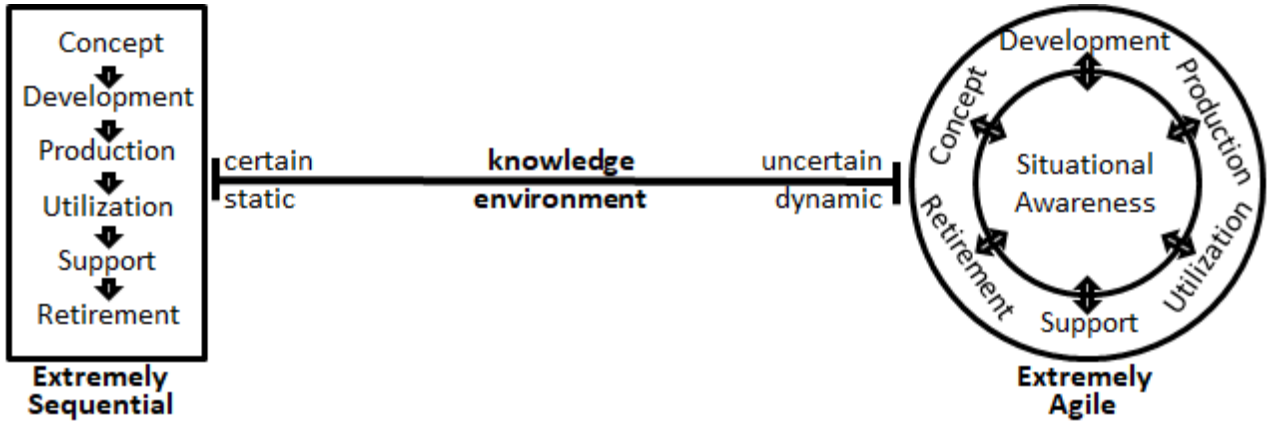

Figure 1. SE life cycle spectrum. (Dove, 2022. Used with permission. All other rights reserved.)

Life Cycle Models

- Lead Author:
- Mike Yokell
- Contributing Authors:
- David Endler and Garry Roedler

-

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. It can be helpful to create models to depict and manage the progression of an entity from beginning to end. These models are called life cycle models.

Life Cycle Models

It can be helpful to create models to depict and manage the progression of an entity from beginning to end. These models are called life cycle models. A life cycle model is a framework of processes and activities concerned with the life cycle which can be organized into stages, acting as a common reference for communication and understanding [SOURCE: ISO/IEC/IEEE 24748-1:2024]

Movement between stages represents a decision point with specific criteria related to stage entry and exit. See Article – Life Cycle Stages for more information. Life cycle models provide a decision-linked segmentation of the conceptualization, development, production, utilization, support, and retirement of the system and its elements.

Any system of interest can be regarded from the perspective of one or more life cycle models. Some life cycle models permit iteration and concurrency of stages while some do not. Which stage(s) a system of interest is in depends on the life cycle model. A system of interest can be in multiple life cycle stages at the same time.

Four common principles associated with a life cycle model are the following:

- a system progresses through specific stages during its life;
- enabling systems should be available for each stage to achieve the outcomes of the stage;
- at specific life cycle stages, quality characteristics such as producibility, usability, supportability and disposability should be specified and designed or implemented into a system;
- stages begin and end based on criteria or external events.

Figure 1 shows models with stage names depending on the context. However, note that some of the models are project models, not life cycle models. That is, they model the phases of a project, not the stages of the life cycle of a system.

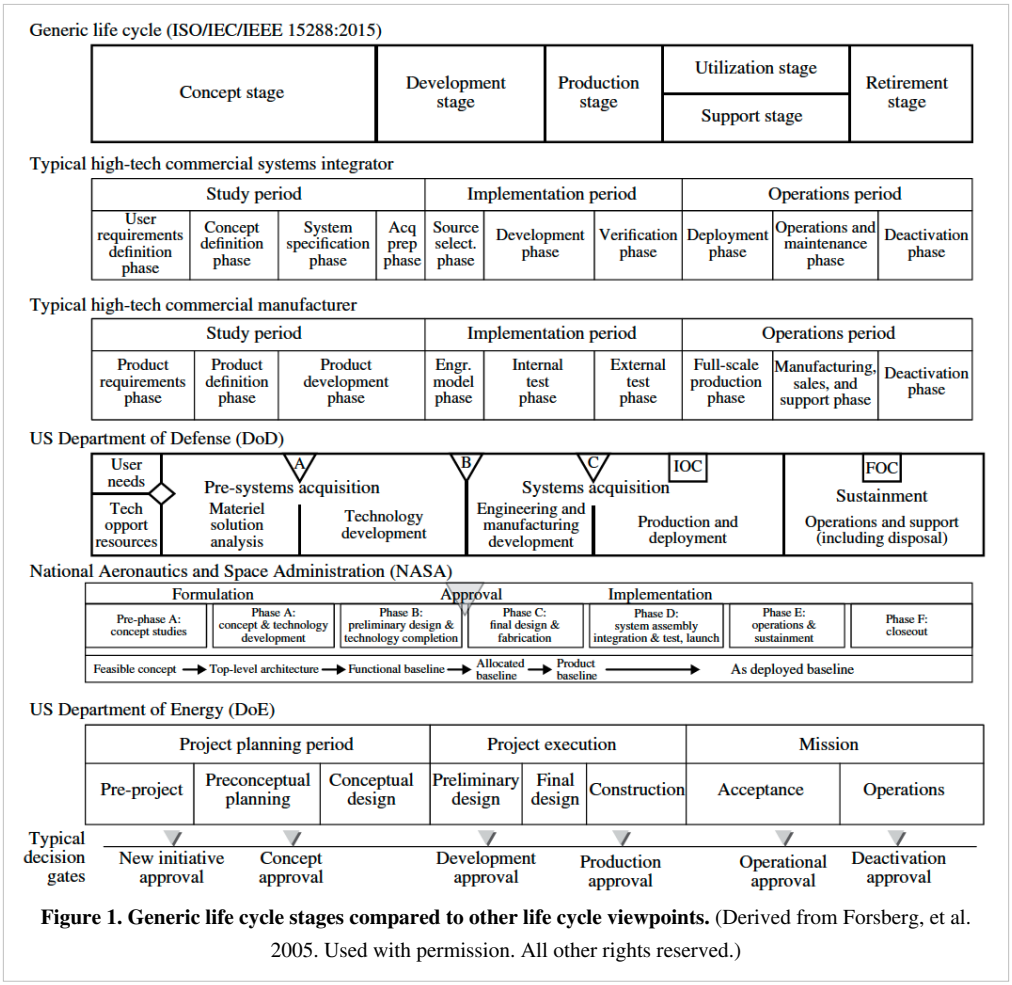

Figure 1. Generic life cycle stages compared to other life cycle viewpoints. (Derived from Forsberg, et al. 2005. Used with permission. All other rights reserved.)

Example

Depending on the life cycle model, stages can occur in parallel and multiple times. Progression through the stages of a life cycle can be depicted in many ways. In Figure 2, the concept stage is short, development and production are longer, while utilization, support, and retirement are lengthy.

In this model for a system of interest where multiple units were produced, utilization and support stages began with the first unit. For the software element, support began during early development, well before delivery to operations. Retirement began when the first unit retired or was lost to damage. In this example the development approach envisioned a mid-life upgrade, so the concept, development and production stages were restarted. Consequently, the support stage ran parallel to utilization until the last unit was removed from service. Support ended while units were still being utilized. The retirement stage continued until the last unit was retired. It is not always possible for the initial developer to know if units are still being utilized.

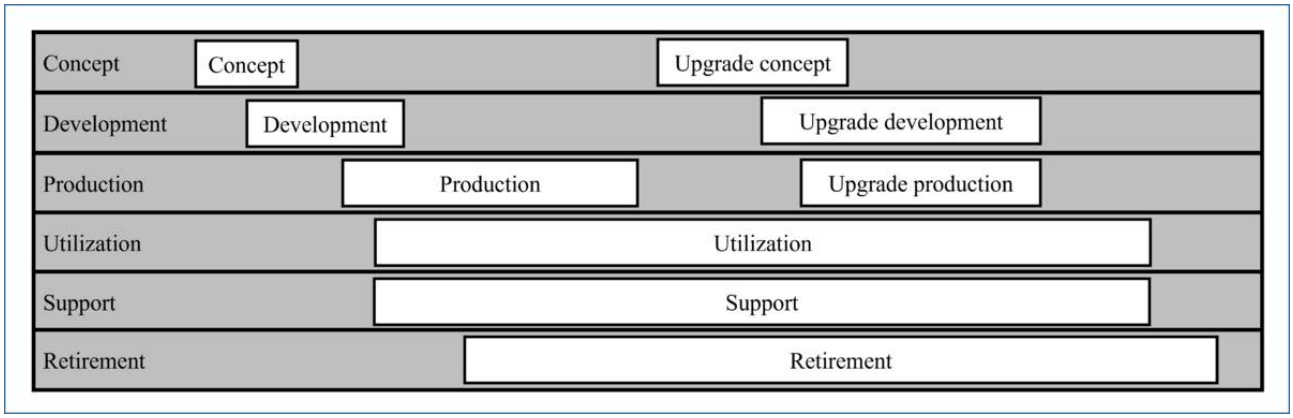

Figure 2. System life cycle stages. (Yokell. Used with permission. All other rights reserved.)

Many life cycle models depict the stages as left to right. DevOps (and DevSecOps) includes a life cycle model that depicts the life cycle stages in an infinity loop as shown in Figure 3. In this model, there is no distinction between development and support; that is, the work is never "done". The model also assumes that the risks and effort associated with retirement are negligible, and thus it does not need to be a focus of the model.

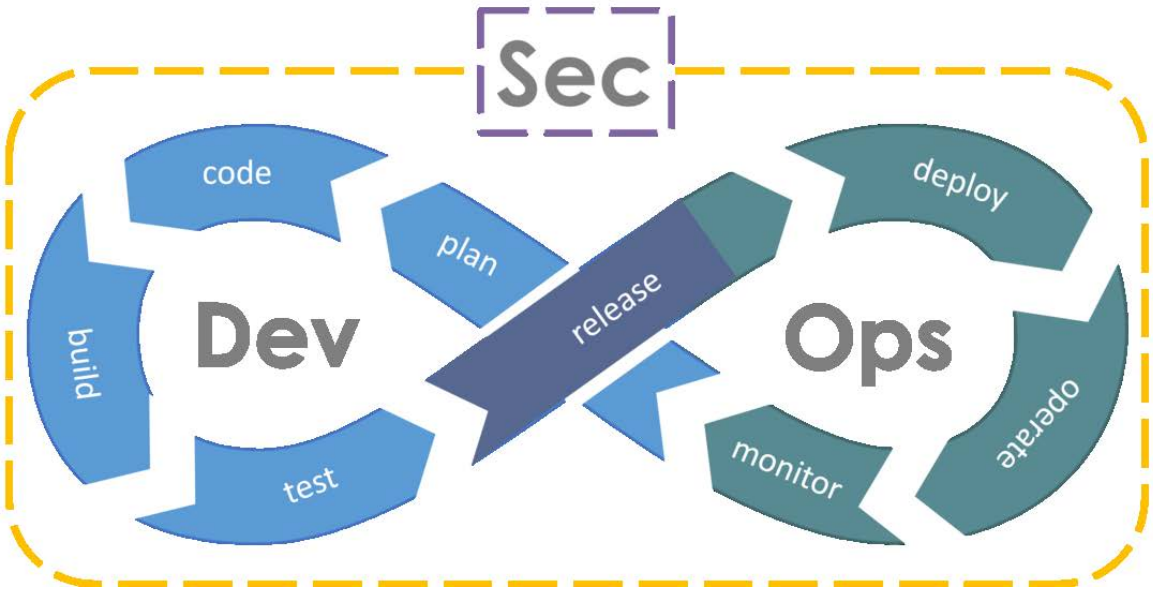

Figure 3. DevSecOps. (D'Souza derived from Banach (2019) and Anx (2021). Used with permission. All other rights reserved.)

Life Cycle Processes

The processes and activities that are integrated into the framework of a life cycle model are often referred to as life cycle processes. They can be seen as one of the enablers to help manage a system solution across the life cycle stages. In some life cycle models the life cycle processes can be applied concurrently, iteratively, and recursively with other enablers (e.g., tools, technology) throughout the stages of the life cycle.

ISO/IEC/IEEE 15288, SAE 1001 and INCOSE SE Handbook define system life cycle processes. In SEBoK, these life cycle processes can be found in KAs Technical Management Processes, System Concept Definition, System Architecture Design Definition, and System Maintenance.

In most cases, organization-specific processes are defined for the life cycle phases in which an organization is usually heavily involved in projects. Organizations that develop systems "from scratch", often have detailed processes to navigate the SoI through the stages Concept and Development. In case the manufacturing of the SoI is

outsourced, the implementation process is rather thin (it cannot be removed as this process is invoked to identify constraints on the SoI related to implementation) and when the organization manufactures the SoI, the implementation process is more detailed.

Life Cycle Stages

- Lead Author:
- Mike Yokell
- Contributing Authors:
- David Endler and Garry Roedler

-

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. (ISO/IEC/IEEE 24748-1) A stage is a period within the life cycle of an entity that relates to the state of its description or realization. Stages relate to major progress, achievement milestones, or decision points of the entity through its life cycle.

Typical Life Cycle Stages

A system progresses through various life cycle stages that span conception, development, production, utilization, support, and retirement. This naming of stages can be found in (ISO/IEC/IEEE 24748-1), (ISO/IEC/IEEE 15288), and the INCOSE *Systems Engineering Handbook* (2023). Within each stage, the primary goals are:

- Concept Stage - Identify stakeholders' needs. Explore concepts. Propose viable solutions
- Development Stage - Refine system requirements. Create solution description. Build system. Perform system verification and system validation
- Production Stage - Produce systems. Inspect and test
- Utilization Stage - Operate system to satisfy users' needs
- Support Stage - Provide sustained system capability
- Retirement Stage - Store, archive or dispose of system

Movement between stages represents a milestone or decision point with specific criteria related to stage entry and exit. Life cycle models provide a decision-linked segmentation of the conceptualization, development, production, utilization, support, and retirement of the system. Any system of interest can be regarded from the perspective of one or more life cycle models. Some life cycle models permit iteration and concurrency of stages while some do not. Which stage(s) a system of interest is in depends on the life cycle model. A system of interest can be in multiple life cycle stages at the same time.

Entry and Exit Criteria

Entry or exit criteria can be met (diamonds in Figure 1) before the decision, concurrent with the decision, after the decision, or not at all (triangles). Decision criteria can include an assessment of technical debt and its implications for other stages. The existence of technical debt in the system negatively impacts design suitability. Technical debt can accumulate in any life cycle stage.

A system life cycle model can be segmented by stages to facilitate planning for the system of interest. Decision-making reviews or gates can be used to inform the progression between stages to reduce risk and to enable satisfactory progress. These gates can be based on specific entry or exit criteria leading to informed decisions that can facilitate consistent outcomes as the system transitions between stages. It is important to note that not all parts of an SOI will reach the same maturity and therefore decision gate at the same time. Therefore, interim maturity reviews are essential to keep timely awareness. Also, it is necessary to be clear about tailoring the entry/exit criteria - one size does not fit all.

At a decision gate, the actual progress is evaluated against criteria expected for each stage or for an increment of the system that can be independent of other increments. Generally, there are two elements to the review: looking

backwards at the progress to date and looking forwards to the preparedness to continue. Criteria determine when a stage can be exited and when other appropriate stages can be begun. Technical Reviews and Audits provides additional information. ISO/IEC/IEEE 24748-8 provides more rigorous requirements for technical reviews and audits in support of decision gates for defense projects but can be applied to other types of systems.

In two-party acquisition situations, joint stakeholder reviews between the parties to the agreement can be needed. These joint reviews can support the decision gates between stages.

Decision Options for each stage:

- Begin another stage or stages
- Continue this stage
- Go to or restart another stage
- Pause activity
- Terminate

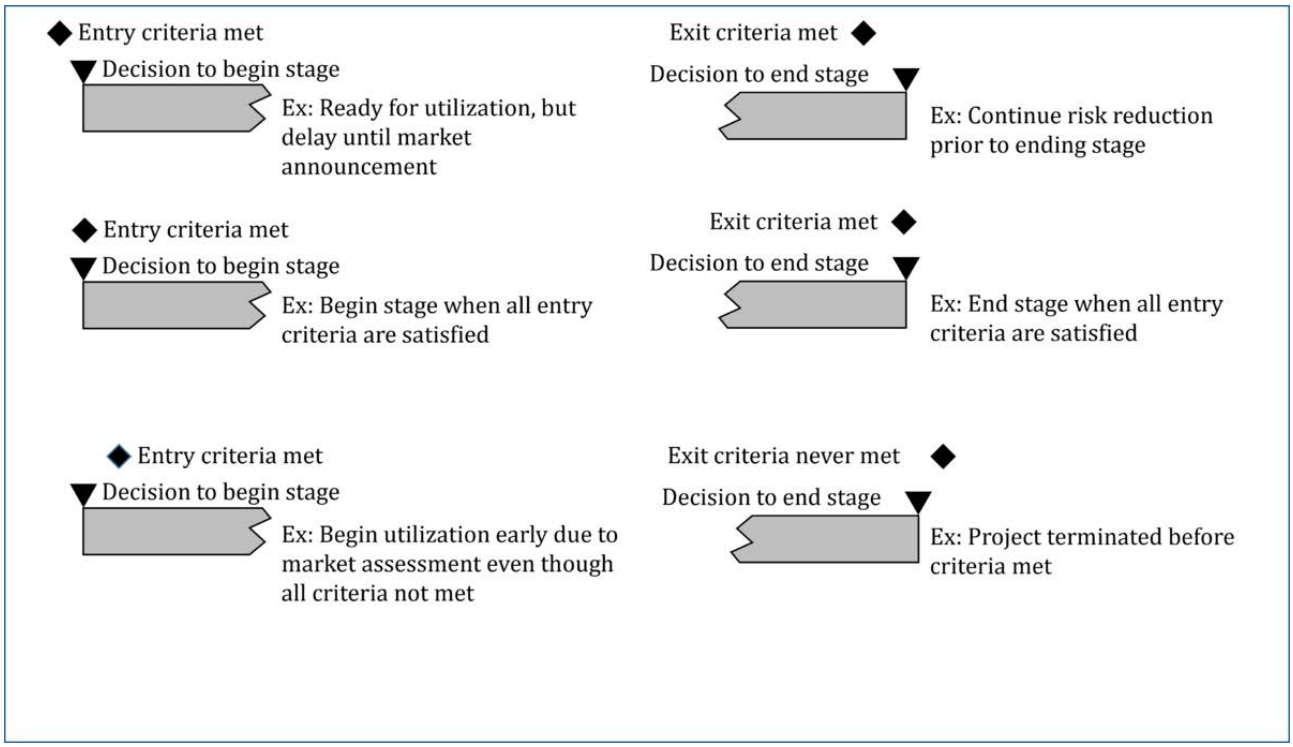

Figure 1. Criteria for decision gates. (Yokell. Used with permission. All other rights reserved.)

Technical Reviews and Audits

- Lead Author:
- Ken Garlington
- Contributing Authors:
- David Endler, Garry Roedler, and Mike Yokell

-

Technical reviews and audits are a mechanism by which sufficiently independent and knowledgeable stakeholders analyze the current state of a system, work product, or set of work products using pre-established criteria. The results of these analyses are used to support programmatic and technical decisions.

Concepts

A technical review is a series of systems engineering activities conducted at logical transition points in a system life cycle, by which the progress of a project is assessed relative to its technical requirements using a mutually agreed-upon set of criteria (ISO/IEC/IEEE 24748-8:2019). An audit is an independent examination of a work product or set of work products to assess compliance with specifications, standards, contractual agreements, or other criteria (ISO/IEC/IEEE 15288:2023). Different organizations, functional disciplines, etc. can use either term or other terms for these related concepts.

Technical reviews and audits support multiple systems engineering processes, including:

- Project assessment and control. Technical reviews and audits help provide visibility into the project's technical progress and risks, and support decision gates by establishing readiness to proceed to the next milestone or life cycle stage.
- Configuration management. Technical reviews and audits support establishing, revising, and verifying configuration baselines.
- Validation. Through the involvement of appropriate stakeholders (including end users), technical reviews and audits enable early validation of requirements, design, and other work products.

Technical reviews and audits can be applied to a system, system element, or other established technical boundary. In addition to their use at transition points in a system life cycle, they can also be used to authorize risky activities, such as testing with safety or security concerns.

Approach

A typical approach to a technical review or audit includes preparing, conducting, and completing it.

Prepare

Technical reviews and audits assess the progress of a project typically include:

- Business case or mission.
- Budget.
- Technical maturity, including associated risks.

These must be balanced to ensure that business and technical baselines are acceptable and will lead to satisfactory verification and validation. The decision as to whether or not to proceed is sometimes associated with great uncertainty. For this reason, it is advisable to properly document the assumptions made and the risks identified.

Technical planning is used to define and coordinate the elements of each technical review or audit, including:

- technical review or audit name,
- purpose and expected outcomes,
- scope (project, system, system element, etc.)
- relevant properties of the system, etc. to be assessed,
- timing and frequency, and
- specific activities and tasks.

To ensure objective and comprehensive results that support the expected outcomes, specific entry and exit criteria should be defined and coordinated, and the completion of the entry criteria confirmed, prior to conducting a technical review and audit (see also Life Cycle Stages and Entry/Exit Criteria). In addition, any necessary independence and areas of expertise required should be considered in the selection and coordination of subject matter experts (SMEs) as participants, including representatives from specialty engineering.

For some key stakeholders, particularly for senior technical and programmatic personnel responsible for a portfolio of projects, a technical review or audit can be a primary method of participating in a project. Planning should consider the needs of these and other stakeholders with respect to specific scheduling, coordination, presentation of project context, etc. Roles and responsibilities for each participant should be coordinated prior to conducting the technical review or audit. Most technical reviews and audits require a set of interrelated information items to be assessed for consistency, completeness, etc. The specific configuration of the information items in the set should be identified and made available to participants as needed prior to conducting the technical review or audit.

According to Boehm and Lane, there are three different types of technical reviews:

Review type	Examples	Considerations
Schedule-based	Explicit dates in agreement	• Opportunities: early and frequent feedback • Risks: insufficient information to meet review objectives, failure to make progress
Event-based	End of development phase (e.g. design) based on delivery of artifacts as defined in agreement	• Opportunities: More complete information available • Risks: Potential for insufficient analysis, unresolved technical issues and risks
Evidence-based	Achieving a specific technical risk level based on supplied evidence	• Opportunities: Higher chance of stakeholder commitment due to more complete risk understanding • Risks: Late feedback on latent defects, etc. with resulting cost, schedule, and technical impacts.

For all of these, there can be misunderstandings or adverse drivers (e.g. schedule, cost) that cause the technical review to be held with insufficient preparation, information, etc.

Conduct

Participants support the purpose and expected outcomes of the technical review or audit through the analysis of relevant information using pre-established criteria. The information may be available as documents, models, simulations, prototypes, or other appropriate formats. Usually, different participants will perform their analysis from different perspectives (safety, security, reliability, etc.) consistent with their expertise. Participants may perform their work independently or as a group. Typically, all participants will meet to discuss analysis results and identify actions based on the results.

In many cases, it can be particularly challenging to identify the right people who are able to objectively assess the outcome of a review. If these people are "too close" to the project, they may be biased (e.g., miss out on the next bonus). If these people are "too far away" from the project, critical issues may not be discovered. Thus, it is most effective to build a review team with a combination of people close enough to provide important insights and some people who are far enough removed to have independent viewpoints.

Complete

Once the exit criteria have been met for the technical review or audit, the results are communicated to the participants (and other stakeholders unable to participate), and any identified actions are implemented as needed to support the desired project outcomes.

Timing and Frequency

Technical reviews and audits can be applied to both a system of interest and recursively to constituent system elements as needed. They can occur sequentially, iteratively, incrementally or concurrently. In any case, they should not be conducted until the pre-defined entry criteria have been met.

Representative Technical Reviews and Audits

Technical reviews and audits are defined based on the needs of the organization, domain, life cycle, etc. Although industry and organizational standards in this area can be useful, they should be carefully tailored for the needs of each project. Example applications are described in:

- United States Department of Defense (DoD) *Systems Engineering Guidebook* (Feb 2022),
- North Atlantic Treaty Organization (NATO) *System Life Cycle Processes* (AAP-48, May 2022),
- National Aeronautics and Space Administration Systems Engineering Processes and Requirements (NPR 7123.1D, Jul 2023), and
- Incremental Commitment Spiral Model

For additional information on applying technical reviews and audits, see ISO/IEC/IEEE 24748-8.

There are various approaches to properly manage the progression of the system of interest (SoI) through its life cycle stages as well as the planning for the other stages. From a systems engineering perspective, the concept and the development stage are of particular interest. For this reason, the articles in this Knowledge Area focus on these two stages. Even though these approaches cover both concept and the development stage, they are often referred to as development approaches. The main difference between the concept stage and the development stage is that the concept stage has a different or more limited set of stakeholders than the development stage.

As projects can have very different starting points, there are a variety of development approaches. In general, the approaches can be roughly divided into sequential, incremental and evolutionary approaches. The agile development approach can be seen as another type or a subset of the others. The boundaries between the groups are not clear-cut and there can be overlaps. The classification is mainly based on the criteria of the extent to which the requirements for the system of interest are known, whether there are increments or not, and what these increments are used for. It is important to keep in mind that development will always be concurrent and iterative to a certain degree.

A life cycle is the evolution of a system, product, service, project or other human-made entity from conception through retirement. (ISO/IEC/IEEE 24748-1) A stage is a period within the life cycle of an entity that relates to the state of its description or realization. Stages relate to major progress, achievement milestones, or decision points of the entity through its life cycle. It can be helpful to create models to depict and manage the progression from beginning to end. These models are called life cycle models.

Basic terms and concepts

A life cycle model is a framework of processes and activities concerned with the life cycle. Each of the life cycle stages has its specific needs and goals. In order to support these, approaches should be in place to ensure continuous learning and improvement. In the context of systems engineering, the development stage is of particular importance. Therefore, this article elaborates on concepts for the development stage.

With the exception of services, the terms "waterfall," "incremental," and "evolutionary" almost always occur adjacent to "development," and almost never adjacent to the names of other life cycle stages (e.g. "waterfall production", "incremental utilization" or "evolutionary retirement". These adjectives apply only to the development stage and not to the life cycle as a whole.

As projects can have very different starting points, there are a variety of development approaches; several with combinations of features including sequential, incremental and evolutionary as shown in Figure 1 below. The boundaries between these groups are not clear-cut and there can be overlaps.

The classification into the groups is mainly based on the criteria of the extent to which the requirements for the system of interest are known, whether there are increments or not, and what these increments are used for. It is important to keep in mind that development will always be concurrent and iterative to a certain degree (which is never zero in practice) as is indicated in Figure 1 by the round symbol along the development stage. In practice, it is often the case that a system of interest consists of system elements for which different development approaches are recommended. This can be caused by most common approaches to hardware and software or even because it has differing delivery goals (e.g., ongoing research vs. in-service support).

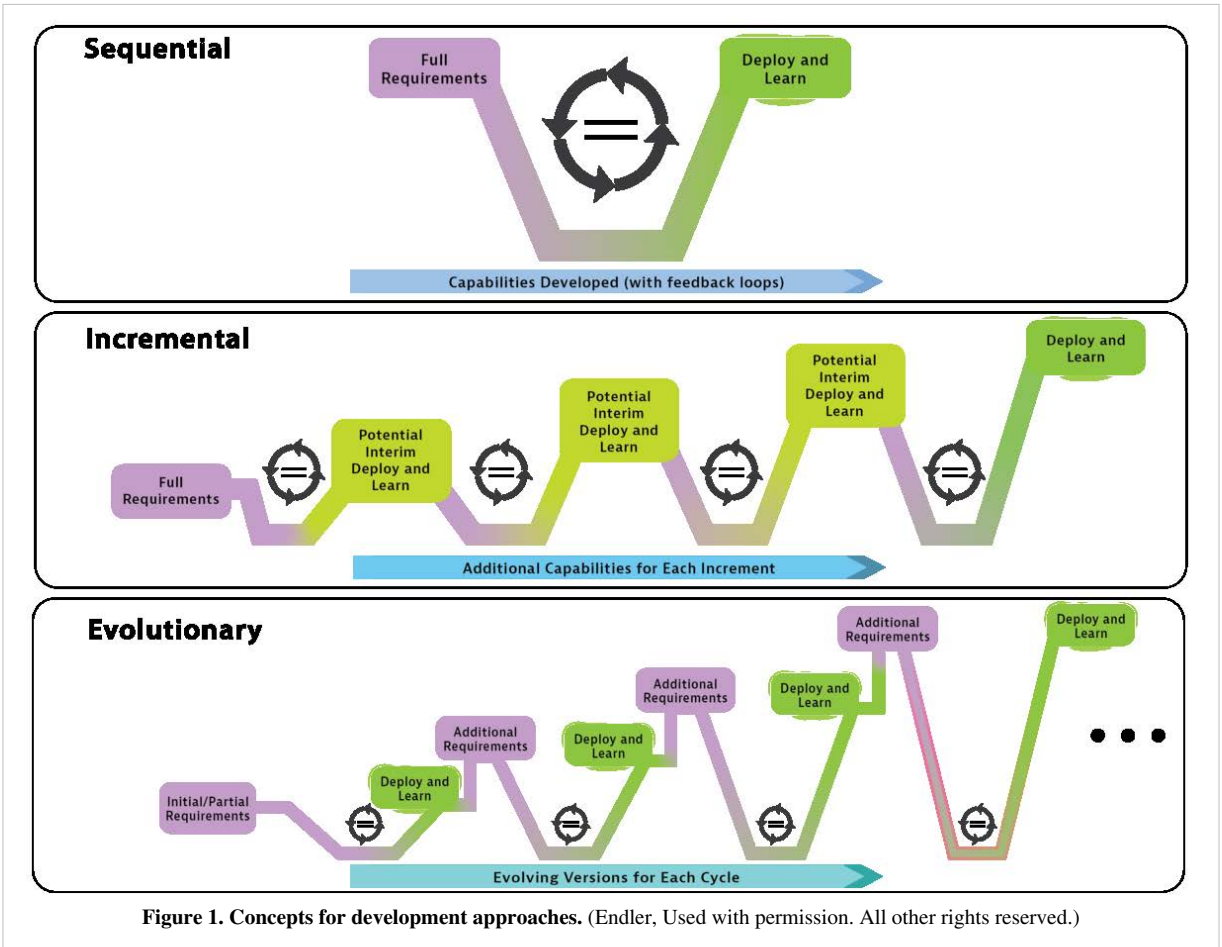

Figure 1. Concepts for development approaches. (Endler, Used with permission. All other rights reserved.)

An agile approach is an iterative and incremental approach to product and service delivery. DevOps (development and operations) is the set of principles and practices which enable better communication and collaboration between relevant stakeholders for the purpose of specifying, developing and operating software, and systems products and services, and continuous improvements in all aspects of the life cycle. Having similar objectives, agile and DevOps approaches are frequently combined.

Agile and DevOps practices are commonly associated with both incremental and evolutionary approaches.

Sequential approaches

Fully sequential approaches are purely theoretical and unfairly maligned because they don't appear in practice. Sequential development approaches typically consist of performing the development tasks in a specific order with some iteration to allow learning and change. Information needs to flow between stages to manage risk. Sequential approaches are intuitive, they have well-defined processes, and it is relatively easy to measure progress. Typically, they are applied to manageable projects in familiar domains where risk is manageable.

Incremental approaches

Incremental approaches are typically applied when a sequence of increments with increasing capabilities or effectiveness are developed. These increments support learning and assessment of potential design solutions. As the development progresses, some of these increments can be released and delivered. The last increment finally meets all requirements and provides all capabilities.

The benefits of incremental approaches are the focus on technical risk and the possibility to introduce emerging technologies.

Evolutionary approaches

Evolutionary approaches start with a limited set of requirements. A series of evolutionary cycles intended to both provide stakeholder value and increase problem understanding is initiated. Each cycle provides an opportunity to examine how the solution is used so the lessons learned can be incorporated in the next iteration.

The benefits of evolutionary approaches are early and steady feedback from stakeholders and the possibility to introduce emerging technologies.

Sequential Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Sequential development approaches are commonly used in complex system development projects. Emphasizing a linear process with some iteration, this approach is particularly suited for large-scale, multi-organization efforts and safety-critical systems. It provides a clear framework for managing system development through distinct, well-defined stages. The article also introduces the Vee model as an example for the sequential development approach. The Vee model is a widely recognized variant that highlights the importance of validation, verification, and stakeholder engagement throughout the development lifecycle. By understanding these models, readers can appreciate the benefits of predictability, repeatability, and high assurance in systems engineering.

Concepts

The sequential development approach is a traditional methodology used in systems engineering, characterized by a structured, phase-based process. One of the earliest and most influential models of this approach is the waterfall model, introduced by Dr. Winston W. Royce in 1970. Interestingly, Royce initially presented the model not as a recommendation, but as a cautionary example of what could go wrong without incorporating feedback and iteration. Nevertheless, it became widely adopted in its linear form.

Royce's waterfall model outlines a series of distinct phases: requirements analysis, system design, implementation (or construction), integration and testing, deployment, and maintenance. Each phase is completed before the next begins, and typically, there is limited overlap or feedback between them. Although Royce advocated for some iteration, particularly early in the process, this aspect was often overlooked in practice.

In systems engineering, sequential development approaches provide structured methods to manage complex projects with well-defined requirements and deliverables. Among the most prominent models are the Waterfall and Vee models. Both offer a clear, phase-driven framework, but they differ in how they handle verification and validation.

The sequential approach is best suited for systems where requirements are well-defined, stable, and unlikely to change during development. It offers a clear structure, thorough documentation, and straightforward progress tracking, making it ideal for projects with strict regulatory, safety, or contractual obligations. This is often the case in industries such as aerospace, healthcare, defense, and civil engineering, where precision, predictability, and traceability are critical.

However, the sequential nature of this approach can make it difficult to accommodate changes once development is underway. Late modifications can be costly and time-consuming, particularly when early decisions are locked in by earlier phases. As a result, this model is most effective in environments with low uncertainty and minimal need for flexibility.

Practical considerations

In systems engineering projects that follow a sequential development approach, especially as originally envisioned by Winston Royce, engineers work within a structured, phase-driven process that incorporates planned iterations, particularly in early phases. While the overall development flow remains sequential, iterations are used to refine requirements and validate early design decisions before full-scale implementation begins.

For systems engineers, this means that early engagement in requirement analysis and system design is critical. Iterative feedback loops during these phases allow for stakeholder input, simulations, and feasibility assessments to inform more accurate and reliable specifications. Engineers must be prepared to revisit and revise these specifications multiple times before moving forward, which requires openness to feedback and strong communication skills.

Once the design is finalized, implementation and integration follow a more linear path. Engineers are expected to execute their tasks based on agreed specifications, with little room for ad hoc changes later in the process. Precision and adherence to documented requirements are essential, as late modifications can affect multiple subsystems and introduce costly rework.

Verification and validation typically occur after integration, so systems engineers must anticipate how subsystems will interact. This demands thorough interface definitions and systems thinking during earlier phases. While iterations are encouraged early on, they are less common in later phases unless major issues arise – underscoring the importance of getting the architecture right before committing to detailed development.

In practical terms, engineers must rely heavily on documentation, formal communication, and system models. Collaboration tends to follow the project structure, with different roles becoming more involved at different points in time. Systems engineers may lead early analysis and design efforts, then shift to supporting roles as implementation and verification proceed.

Ultimately, working within this approach requires a disciplined mindset, a proactive attitude during early iterations, and a strong focus on requirements traceability and design integrity throughout the project lifecycle.

Example development approach

The Vee model was developed as an extension of the Waterfall model to address the concerns that late discovery of defects or requirement mismatches can be costly. The Vee model retains a sequential flow but integrates system verification and validation more explicitly. As shown in Figure 1, it visualizes development in a “V” shape.

Note that because the Vee Model only covers the development stage, and not the full life cycle, it is not a life cycle model. There are other forms of the Vee model that show feedback from the right side of the Vee to the left side of the Vee for validation and verification.

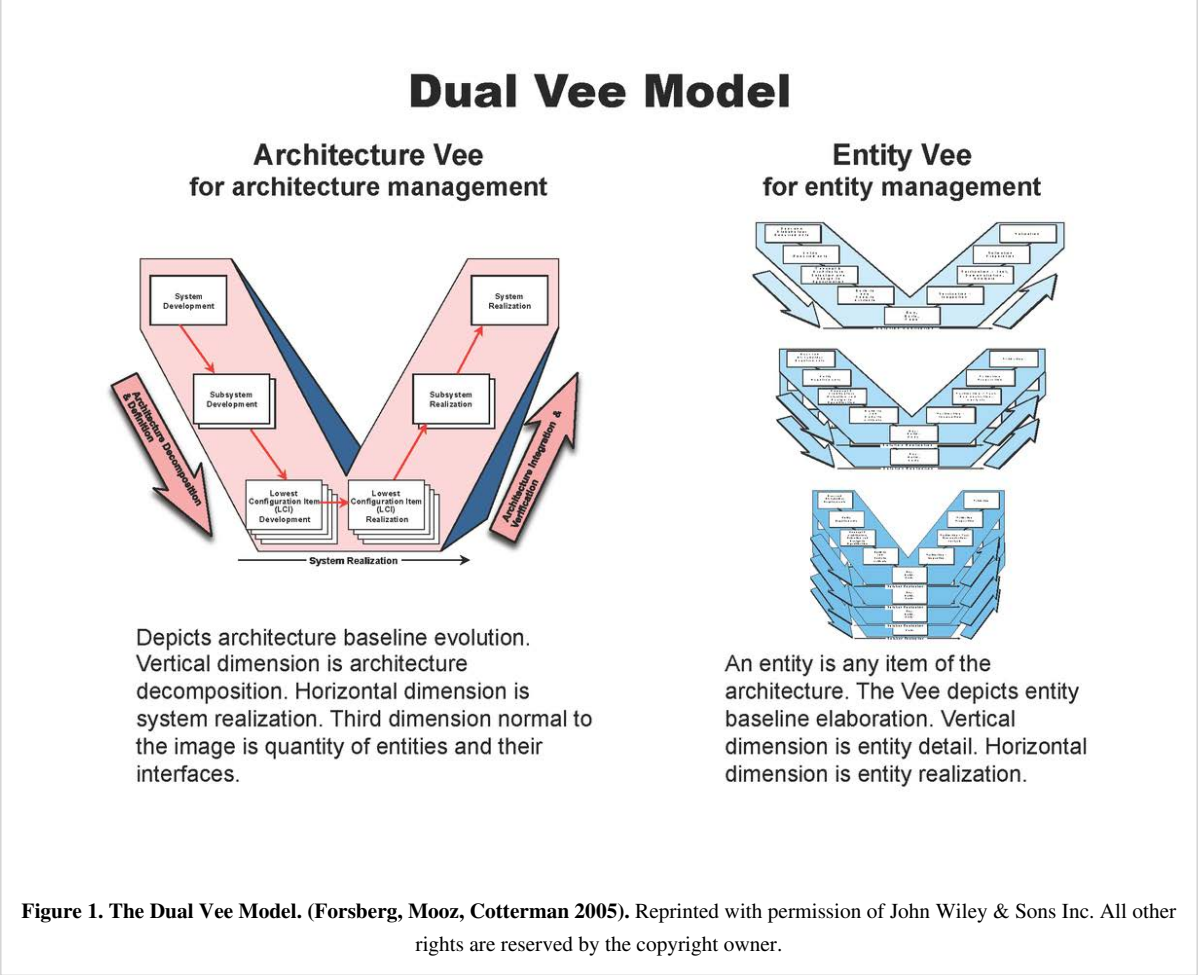

Figure 1. The Dual Vee Model. (Forsberg, Mooz, Cotterman 2005). Reprinted with permission of John Wiley & Sons Inc. All other rights are reserved by the copyright owner.

The Vee model is used to visualize key areas for SE focus, associating each development stage with corresponding verification. The Vee highlights the need for continuous validation with the stakeholders, the need to define verification plans during requirements development, and the importance of continuous risk and opportunity assessment.

There are several variations of the Vee model. Typically, the “left” side of the Vee is called system definition and the “bottom” and “right” side of the Vee are called system realization. In the Vee model, time and system maturity conceptually proceed from left to right (down the left side of the Vee and up the right side of the Vee). However, all the system life cycle processes are performed concurrently and iteratively at each level of the system hierarchy and all the system life cycle processes are recursively applied at each level of the system hierarchy. One of the strengths of the Vee model is its depiction of the relationships between the left and right sides of the Vee.

The Vee model is widely used in systems engineering because it makes the relationship between development, verification, and validation more explicit. It encourages engineers to think ahead about how each part of the system will be verified, helping to reduce the risk of late failures.

Incremental Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Incremental development approaches offer a flexible and adaptive method suited for projects with high uncertainty or evolving requirements. Unlike sequential models, incremental development delivers value in chunks by breaking down the system into manageable increments, each providing a subset of capabilities. This allows for potential early deployment, faster feedback, and continuous improvement based on real-world insights. The article explores practical applications, planning challenges, and the importance of balancing a structured roadmap with flexibility. It also highlights the Incremental Commitment Spiral Model (ICSM), which integrates concurrent development and risk assessment to guide informed decisions across successive development cycles.

Concepts

Incremental development is a fundamental approach in systems engineering where a system evolves through repeated cycles (iterations) of planning, designing, implementing, and evaluating. Unlike sequential approaches, such as the Waterfall model, incremental development approaches allow for continuous refinement of both requirements and solutions based on feedback and learning obtained during each iteration.

The roots of incremental development can be traced back to the 1950s and 60s with early software and systems engineering projects that required more flexibility than rigid linear models could provide. Notably, Barry Boehm's Spiral Model in the 1980s formalized incremental development by emphasizing risk management and incremental progress. It later influenced many agile and incremental development methodologies used today.

When using an incremental approach, not every iteration results in a tangible increment (i.e., a deliverable or prototype). Some iterations serve primarily as learning opportunities -exploring technical feasibility, user needs, or integration challenges. These learning-focused cycles are crucial for reducing uncertainty and guiding future design decisions.

Iterations that do produce increments provide stakeholders with early, partial versions of the system. These early deliverables enable verification, validation, and feedback well before the final system is complete. This responsiveness to change and focus on incremental value helps ensure the system better meets user needs and environmental constraints.

Incremental development approaches are especially useful in complex, high-uncertainty projects such as those involving new technologies, evolving requirements, or significant stakeholder interaction. It supports a more adaptive planning process, enabling engineers to respond to change and reduce risks over time.

By embracing early feedback, learning, and flexibility, incremental development approaches help create more robust, user-centered systems. It aligns engineering efforts with real-world complexities, making it a powerful strategy for certain development environments.

Practical considerations

The incremental development approach typically determines user needs, defines requirements, then divides the remaining development into a series or sequence of iterations, some of which result in a tangible increment and some of which serve for learning.

Early iterations may focus more on exploration (modeling, simulation, or proof-of-concept studies) to reduce technical uncertainty or evaluate design alternatives. Systems engineers must be comfortable with partial or evolving system architectures, often working with incomplete data or preliminary interfaces.

Traceability and configuration management also take on a different character compared to a sequential development approach. Since requirements, design elements, and interfaces may evolve over several iterations, robust version control and clear documentation of assumptions and decisions become essential to prevent confusion or rework later.

Collaboration and communication are especially critical. Incremental development often involves frequent interactions with stakeholders, users, and other engineering disciplines. Systems engineers must facilitate this exchange, using tools like prototypes, models, or incremental demonstrations to ensure alignment across the team and with the project goals.

Validation and verification activities are also distributed more evenly across the project timeline. Rather than being concentrated at the end, these activities are planned into iterations, allowing for early detection of issues. This demands more flexible test planning and a willingness to revise test cases as the system evolves.

Proper planning of the increments is critical and at the same time challenging. On the one hand, stakeholders are expecting a “master plan” for the increments and on the other hand, subsequent increments build on the learnings from the previous increments.

Finally, engineers must be prepared to continuously reassess risks and priorities at each iteration boundary. Trade studies, system impact assessments, and integration planning become recurring tasks, helping to maintain system coherence and feasibility across changing project conditions.

An incremental development approach can also be used when it is critical to hit the market with a product at a certain point in time. In this case, it can be advantageous to bring a product with limited capabilities to the market to get “a foot in the door”. Successive increments follow to close the capability gaps.

Example development approach

Boehm’s Incremental Commitment Spiral Model (ICSM) shown in Figure 1 is a modern incremental approach which extends the classic Spiral Model (Boehm, 1987) for software introduced by Boehm for SE. It is designed to address the challenges of complex, high-risk systems engineering projects. It combines the strengths of traditional, plan-driven methods with the flexibility of iterative and agile practices, offering a structured way to deliver systems in well-defined increments while continuously managing uncertainty and stakeholder alignment.

In ICSM, system development is divided into a series of incremental cycles, each leading to a decision point, or commitment review. Rather than committing to a full system design early on, stakeholders and engineers make incremental commitments only as far as the evidence and confidence gathered in each cycle justify. This allows projects to pivot, refine goals, or even stop development early if feasibility or value cannot be demonstrated.

Each cycle involves activities such as stakeholder engagement, feasibility assessments, risk analysis, and prototype development. If the results are promising, the project moves forward to the next increment, where additional capability is developed and validated. Over time, the system grows in maturity and functionality, reducing risk at each stage.

Unlike purely iterative models, ICSM provides clear decision checkpoints and is especially useful in projects requiring formal reviews, traceability, and accountability such as in defense, transportation, or critical infrastructure systems. It accommodates evolving requirements while maintaining a disciplined engineering process.

For systems engineers, working with ICSM means managing incremental baselines, tracking decisions across cycles, and facilitating informed stakeholder commitments. The model encourages early and continuous validation, with learning cycles embedded throughout the project.

Evolutionary Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

The evolutionary development approach is a dynamic and flexible method ideal for projects where not all requirements are known upfront and are likely to evolve over time. Unlike sequential or incremental models, evolutionary development embraces uncertainty, allowing systems to evolve through frequent iterations and stakeholder feedback. Often applied in software development, this approach emphasizes rapid delivery of deployable versions and continuous refinement based on user input. Key considerations include managing compatibility, supporting multiple versions, and designing with adaptability and modularity in mind. The article also highlights DevOps as a representative model, showcasing how continuous integration, automation, and shared ownership drive ongoing development and operational excellence.

Concepts

Evolutionary development approaches are a flexible strategy for developing complex systems in situations where only part of the system's requirements is known at the start. Unlike sequential development approaches that aim to finalize all specifications before implementation begins, this approach allows the system to evolve over time driven by real-world use and continuous feedback.

Emerging in the late 1970s and early 1980s, evolutionary development gained recognition as an effective way to handle uncertainty and changing needs in system design. It has since become widely adopted across industries where adaptability and responsiveness are essential.

In evolutionary development, systems are developed, built, and delivered in a series of working iterations, each of which is released to the market or end users. These early versions provide core functionality and are intended for actual use. Feedback from users, performance data, and market response are gathered and analyzed after each release. This insight is then used to shape the next version of the system.

Each iteration adds new capabilities or improves existing ones, gradually expanding and refining the system. Because the system is in use from early on, stakeholders can interact with real products rather than abstract plans, which helps clarify needs and priorities as development progresses.

This approach is especially effective for innovative or dynamic markets, where requirements are likely to change and speed of delivery is important. It reduces risk by allowing early validation and ensures the system remains aligned with user expectations and market demand.

Key characteristics of evolutionary development include frequent releases, real-world feedback loops, and continuous improvement. It's best suited for projects where the ability to adapt quickly and learn from use is critical to success.

Practical considerations

One key consideration is modular and scalable architecture. Since the system will grow and change over multiple iterations, it must be designed to accommodate extension and modification without major rework. Interfaces should be well-defined and loosely coupled to allow new system elements to integrate smoothly as they are developed.

Another critical aspect is continuous integration and verification. Each iteration is intended for release and real-world use, so it must meet quality standards independently. Systems engineers must ensure that each version is sufficiently verified and that the integration of new system elements does not compromise overall functionality, safety, or compliance. This often involves setting up automated testing frameworks, simulation environments, and regression test suites early in the project.

Traceability and configuration management also take on increased importance. As requirements evolve and the system matures, maintaining clear documentation of what was changed, why it was changed, and what impact it had becomes essential. Systems engineers must use version control systems and maintain accurate configuration baselines across iterations. This discipline not only supports accountability and regulatory compliance but also enables engineers to assess the upgradeability of deployed systems ensuring that new versions can be integrated smoothly into existing operational environments without disrupting functionality or compatibility.

Finally, close and ongoing collaboration with stakeholders is vital. Systems engineers need to actively participate in feedback loops, assess input from the field, and translate user experiences into actionable technical changes. This requires not only technical expertise but also strong communication skills and a user-focused perspective.

Example development approach

Although DevOps as shown in Figure 1 is a set of principles, it is often cited as an example of evolutionary development approaches. At the same time, DevOps can also be understood as a lifecycle model, as it is an infinite repetition of development and operations.

An evolutionary approach to system development focuses on building systems in a way that allows continuous adaptation to changing requirements, user feedback, and external conditions. DevOps is a prime example of an evolutionary approach that blends development, operations, and continuous feedback loops to improve systems over time.

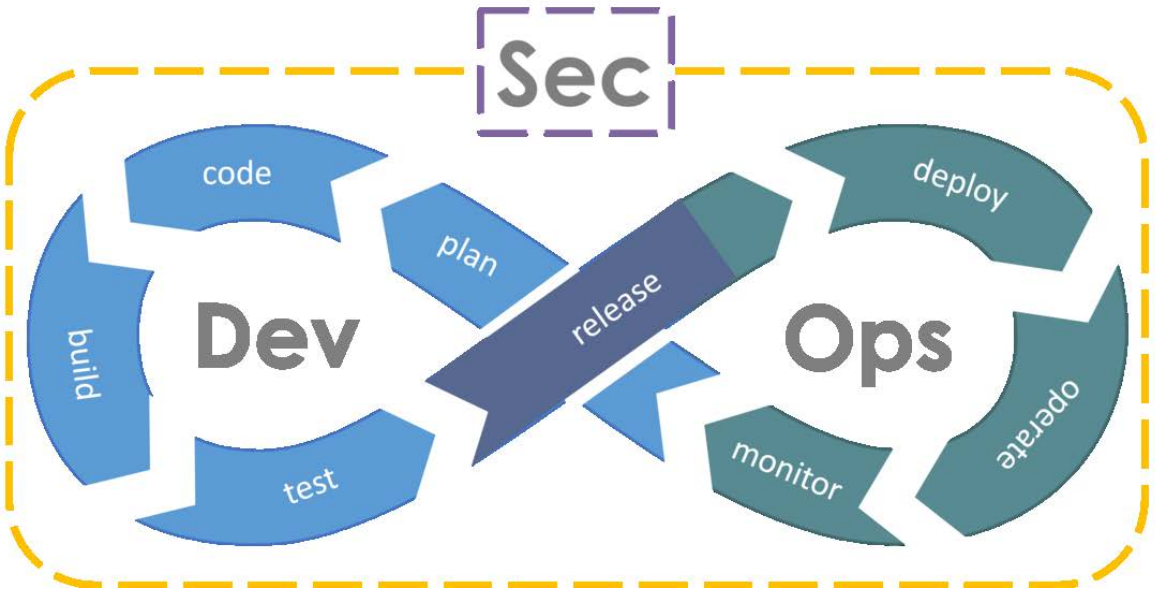

Figure 1. DevSecOps. (D'Souza derived from Banach (2019) and Anx (2021). Used with permission. All other rights reserved.)

As shown in the figure, DevOps promotes continuous integration (CI) and continuous delivery (CD), enabling rapid iteration and frequent releases of system updates. The core idea is to create a development pipeline where small, incremental changes are integrated and tested continuously, making it possible to deploy new features or fixes to production at any time. This method allows the system to evolve based on real-time feedback, whether from users, monitoring tools, or the operational environment.

For systems engineers, DevOps means engaging in constant collaboration with both development and operations teams. It's not just about writing code or designing systems in isolation; it's about iteratively building a system, deploying it into the real world, gathering data, and refining it based on that data. Automation plays a crucial role in DevOps, as it ensures that the evolution process is both fast and reliable. Automated tests, deployment pipelines, and infrastructure-as-code practices enable engineers to deliver frequent updates without sacrificing quality.

DevOps also emphasizes the importance of feedback loops whether it's from customers, users, or system performance monitoring. As the system is deployed and used, systems engineers can gather actionable insights that inform subsequent iterations. This continuous cycle of building, deploying, testing, and adapting is the essence of the evolutionary development approach.

In environments like cloud services, IoT systems, or large-scale software platforms, where conditions are constantly changing and innovation is rapid, DevOps offers a practical, scalable way to ensure systems remain relevant and high performing over time.

Agile Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Agile development is an approach based on iterative development, frequent inspection and adaptation, and incremental deliveries in which requirements and solutions evolve through collaboration in cross-functional teams and through continual stakeholder feedback.

Concepts

Agile simply means able to move quickly and easily. Agile is an adjective, as in an agile development approach or an agile person. Agility is a noun, as in systems engineering agility, or someone who has impressive agility for a person of their size.

Agile development is an approach based on iterative development, frequent inspection and adaptation, and incremental deliveries in which requirements and solutions evolve through collaboration in cross-functional teams and through continual stakeholder feedback (ISO/IEC/IEEE 26515).

Iteration is repeating the application of the same process or set of processes on the same level of the system structure (ISO/IEC/IEEE 15288:2023).

In contrast to sequential approaches, agile development approaches break development into small, manageable units of work called iterations or sprints, usually lasting 1 to 4 weeks. At the end of each iteration, the team delivers a potentially shippable product increment. This allows for frequent reassessment of priorities and adaptation to new information or customer needs.

Agile principles were formally introduced in 2001 with the publication of the Agile Manifesto [1], which was specifically designed for software development. The Manifesto outlines four core values for guiding the development of software systems:

1. Individuals and interactions over processes and tools
2. Working systems over comprehensive documentation
3. Customer collaboration over contract negotiation
4. Responding to change over following a plan

While these values were crafted for software development, many systems engineers adopt agile principles in their practices. However, it is important to recognize that these principles were initially formulated within the context of software engineering and may not transfer seamlessly to the broader, more complex domain of systems engineering. Systems engineering involves not only software but also hardware, human elements, processes, and other components that may require different considerations, timelines, and integration points.

The agile methodology is supported by 12 principles that emphasize continuous delivery, responsiveness to change, and high-quality, sustainable development practices. However, these principles were originally intended for software systems, and the direct application of these ideas to complex systems engineering projects can require adaptation. Agile methods can be highly effective in dynamic environments where customer needs evolve rapidly. Teams are encouraged to deliver value early and often, potentially improving responsiveness and customer satisfaction. At the same time, these approaches must be carefully adapted when applied to large-scale, multi-disciplinary systems engineering projects.

Practical considerations

In an agile systems engineering environment, team members collaborate in a fast-moving, feedback-driven manner. A core aspect of agile systems engineering is the use of system-level user stories. These are short, simple descriptions of system features or capabilities from the perspective of the end user. Each story typically follows a format like: “As a <role (who wants to accomplish something)>, I want <activity (what they want to accomplish)> so that <business value (why they want to accomplish that thing)>.” These stories help clarify not just the technical requirements but also the rationale behind them.

User stories are often grouped into user journeys or epics, giving context to how individual features contribute to the broader product experience. During sprint planning, the team breaks stories into smaller tasks, estimates their complexity (often using story points), and commits to what can realistically be delivered in the upcoming sprint. Frequent communication is vital in agile systems engineering to share progress, identify obstacles, and coordinate efforts, ensure alignment and foster transparency.

Using an agile development approach also means team members are expected to respond to change. As requirements evolve throughout the project, teams are expected to pivot and adjust without disrupting the overall progress. Continuous engagement with stakeholders, including system architects, designers, and product owners, ensures that changing priorities are clearly communicated and understood.

Sprints are a core element of most agile methodologies, but there are some agile approaches that do not strictly rely on sprints. In case sprints are used, retrospectives at the end of each sprint allow team members to reflect on their processes, discuss what worked well, and identify areas for improvement. This fosters a culture of continuous learning and refinement, encouraging ongoing process optimization. In the agile development approach, decision points tend to avoid the terms "milestones" and "decision gates." With agile development approaches, interaction with stakeholders can be more frequent, smaller in scope and less formal than other approaches. (ISO/IEC/IEEE 24748-1)

Example development approach

Several frameworks have emerged to help teams implement agile principles effectively. The following text introduces a few non-exhaustive examples to demonstrate the existing variation in agile methods and do not constitute an endorsement.

Scrum [2] is the most widely used. It structures work into time-boxed sprints (sometimes 2 to 4 weeks) and includes defined roles such as Product Owner, Scrum Master, and Development Team. Scrum emphasizes clear priorities, daily stand-ups, sprint planning, reviews, and retrospectives to promote continuous improvement and team alignment.

For larger organizations, SAFe (Scaled Agile Framework) [3] provides a structured way to scale Agile across multiple teams and departments. It introduces roles like Release Train Engineer and events like PI Planning (Program Increment Planning), aligning teams around shared goals and synchronized delivery cycles. SAFe blends Agile, Lean, and systems thinking to support complex enterprise needs.

LeSS (Large-Scale Scrum) [4] is a lighter-weight alternative to SAFe. It extends Scrum principles to multiple teams working on the same product. Instead of adding layers of management, LeSS encourages simplification and emphasizes team autonomy and shared product ownership.

Each framework offers different levels of structure, but all aim to improve collaboration, transparency, and adaptability which are key benefits of working in an Agile environment.

Figure 1 shows an example of a mixed approach that is both incremental, evolutionary and agile. In this example, teams working on electronic-board hardware, firmware, and software have different timings for hardware increments and firmware and software epics (versions). The teams accomplish integrated work-in-process test with the latest increments and versions from each of the disciplines.

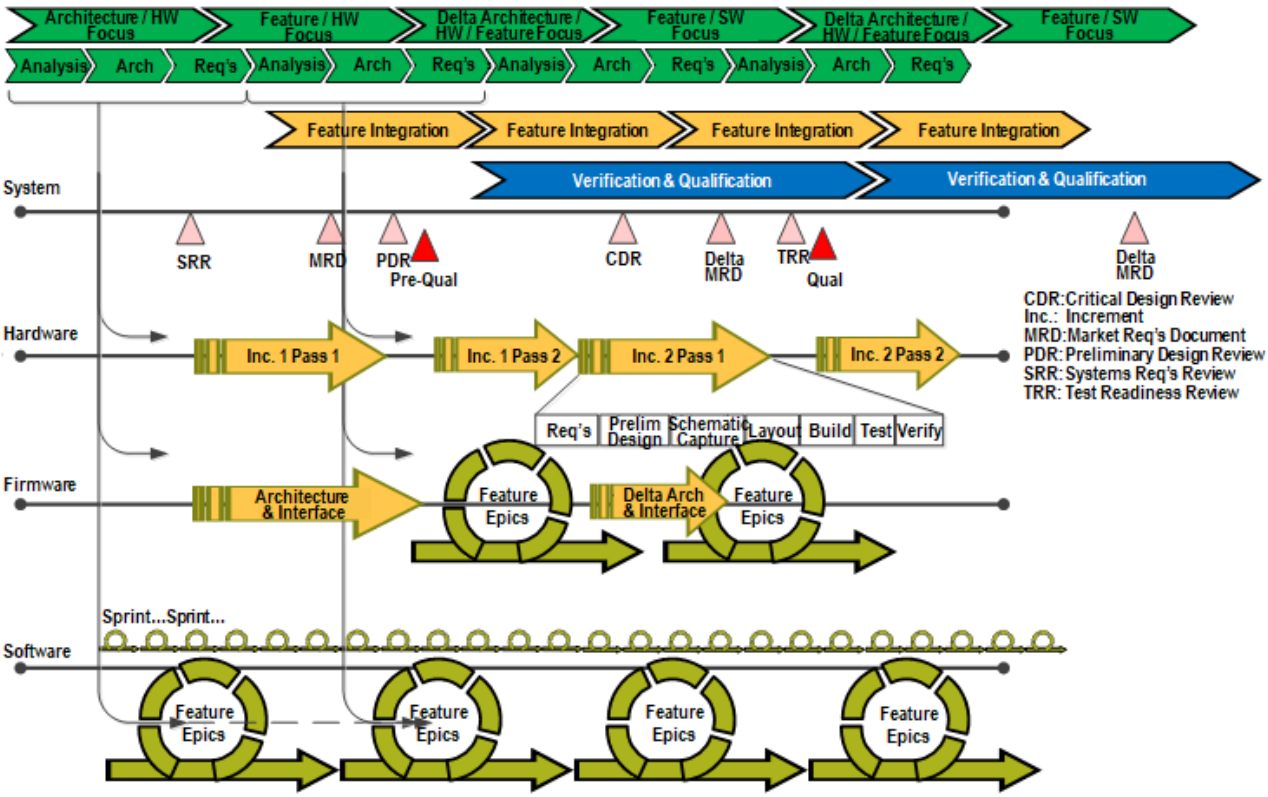

Figure 1. Asynchronous iterations and increments across agile mixed discipline engineering. (Dove, et al. (2017). Used with permission. All other rights reserved.)

This example shows bringing the individual strands together at certain points in time. This reduces inconsistencies at the interfaces and strengthens the team spirit.

Lean Engineering

-

Lean Systems Engineering (LSE) is the application of lean thinking (Womack 2003) to systems engineering (SE) and related aspects of enterprise and project management. LSE is an approach that is applicable throughout the system life cycle. The goal of LSE is to deliver the best life-cycle value for technically complex systems with minimal waste. Lean engineering is relevant to all of the traditional SE technical processes (see system concept definition, system definition, system realization, system deployment and use, etc.). Lean engineering also interacts with and utilizes many of the specialty engineering disciplines discussed in Part 6.

Lean Systems Engineering

SE is an established, sound practice, but not always delivered effectively. Most programs are burdened with some form of waste such as: poor coordination, unstable requirements, quality problems, delays, rework, or management frustration. Recent U.S. Government Accountability Office (GAO), National Aeronautics and Space Association (NASA), and Massachusetts Institute of Technology (MIT) studies of government programs document major budget and schedule overruns and a significant amount of waste in government programs - some reaching seventy percent of charged time. This waste represents a productivity reserve in programs and major opportunities to improve program efficiency.

LSE is the application of lean thinking to systems engineering and related aspects of enterprise and project management. SE is focused on the discipline that enables development of complex technical systems. Lean thinking is a holistic paradigm that focuses on delivering maximum value to the customer and minimizing wasteful practices. It has been successfully applied in manufacturing, aircraft depots, administration, supply chain management, healthcare, and product development, which includes engineering. LSE is the area of synergy between lean thinking and SE, which aims to deliver the best life-cycle value for technically complex systems with minimal waste. LSE does not mean less SE. It means more and better SE with higher responsibility, authority, and accountability (RAA), leading to better, waste-free workflow with increased mission assurance. Under the LSE philosophy, mission assurance is non-negotiable and any task which is legitimately required for success must be included; however, it should be well-planned and executed with minimal waste.

Lean Principles

Oppenheim (2011) describes the six lean principles for product development (PD) as follows:

1. **Capture the *value* defined by the customer.** One cannot over-emphasize the importance of capturing task or program value (requirements, CONOPS, etc.) with precision, clarity, and completeness before resource expenditures ramp up to avoid unnecessary rework.
2. ***Map the value stream (plan the program)* and eliminate waste.** Map all end-to-end linked tasks, control/decision nodes, and the interconnecting information flows necessary to realize customer value. During the mapping process, eliminate all non-value-added activities, and enable the remaining activities to flow (without rework, backflow or stopping). The term *information flow* refers to the packets of information (knowledge) created by different tasks and flowing to other tasks for subsequent value adding, such as: design, analysis, test, review, decision, or integration. Each task adds value if it increases the level of useful information and reduces risk in the context of delivering customer value.
3. ***Flow* the work through planned and streamlined value-adding steps and processes, without stopping or idle time, unplanned rework, or backflow.** To optimize flow, one should plan for maximum concurrency of tasks, up to near capacity of an enterprise. Legitimate engineering iterations are frequently needed in PD, but they tend to be time consuming and expensive if they extend across disciplines. Lean PD encourages efficient methodology of *fail early - fail often* through rapid architecting and discovery techniques during early design phases. Lean flow also makes every effort to use techniques that prevent lengthy iterations, such as design frontloading, trade space explorations, set designs, modular designs, legacy knowledge, and large margins. Where detailed cross-functional iterations are indeed necessary, lean flow optimizes iteration loops for overall value.
4. **Let customers *pull* value.** In PD, the pull principle has two important meanings: (1) the inclusion of any task in a program must be justified by a specific need from an internal or external customer and coordinated with them, and (2) the task should be completed when the customer needs the output. Excessively early completion leads to “shelf life obsolescence” including possible loss of human memory or changed requirements and late completion leads to schedule slips. This is the reason that every task owner or engineer needs to be in close communication with their internal customers to fully understand their needs and expectations and to coordinate their work.
5. **Pursue *perfection* of all processes.** Global competition requires continuous improvements of processes and products. Yet, no organization can afford to spend resources improving everything all the time. Systems engineers must make a distinction between processes and process outputs. Perfecting and refining the *work output* in a given task must be bounded by the overall value proposition (system or mission success, program budget and schedule) which define when an output is "good enough." In contrast, engineering and other *processes* must be continuously improved for competitive reasons.
6. ***Respect* for people.** A lean enterprise is an organization that recognizes that its people are the most important resource. In a lean enterprise, people are not afraid to identify problems and imperfections honestly and openly in real time, brainstorm about root causes and corrective actions without fear, or plan effective solutions together by consensus to prevent a problem from occurring again.

Lean Enablers for Systems

In 2009, the International Council on Systems Engineering's (INCOSE's) Lean SE Working Group (LSE WG) released an online product entitled *Lean Enablers for Systems Engineering (LEfSE)*. It is a collection of practices and recommendations formulated as “dos” and “don’ts” of SE, based on lean thinking. The practices cover a large spectrum of SE and other relevant enterprise management practices, with a general focus on improving the program value and stakeholder satisfaction and reduce waste, delays, cost overruns, and frustrations. LEfSE are grouped under the six lean principles outlined above. The LEfSE are not intended to become a mandatory practice but should be used as a checklist of good practices. LEfSE do not replace the traditional SE; instead, they amend it with lean thinking.

LEfSE were developed by fourteen experienced INCOSE practitioners, some recognized leaders in lean and SE from industry, academia, and governments (such as the U.S., United Kingdom, and Israel), with cooperation from the 160-member international LSE WG. They collected best practices from the many companies, added collective tacit knowledge, wisdom, and experience of the LSE WG members, and inserted best practices from lean research and literature. The product has been evaluated by surveys and comparisons with the recent programmatic recommendations by GAO and NASA.

Oppenheim (2011) includes a comprehensive explanation of the enablers, as well as the history of LSE, the development process of LEfSE, industrial examples, and other material. Oppenheim, Murman, and Secor (2011) provide a scholarly article about LEfSE. A short summary was also published by Oppenheim in 2009.

-

Agile systems engineering (Dove et al, 2023, ISO/IEC/IEEE 24748-10) is a principle-based method for designing, building, sustaining, and evolving systems when knowledge is uncertain and/or environments are dynamic. Agile systems engineering is being agile, not doing agile. Thus, Agile System Engineering is a what, not a how.

Concepts

The common use of the terms agile and agility are fundamental to its application in systems engineering. Agile simply means able to move quickly and easily. Agile is an adjective, as in an agile development approach or an agile person. Agility is a noun, as in systems engineering agility, or he has impressive agility for a person of his size.

Within systems of software engineering, agile is a development approach based on iterative development, frequent inspection and adaptation, and incremental deliveries in which requirements and solutions evolve through collaboration in cross-functional teams and through continual stakeholder feedback (ISO/IEC/IEEE 24748-1:2024, 3.4)

Likewise, Systems engineering (SE) agility is a “strategy-based method for designing, building, sustaining, and evolving purpose-fulfilling creations when knowledge is uncertain and operational environments are dynamic” (Dove et al, 2023, ISO/IEC/IEEE 24748-10). Agile SE is a thoughtful engagement with opportunities and threats in the environment. Figure 1 shows a spectrum of life cycle approaches. All life cycle approaches fall somewhere between the two ends of the spectrum.

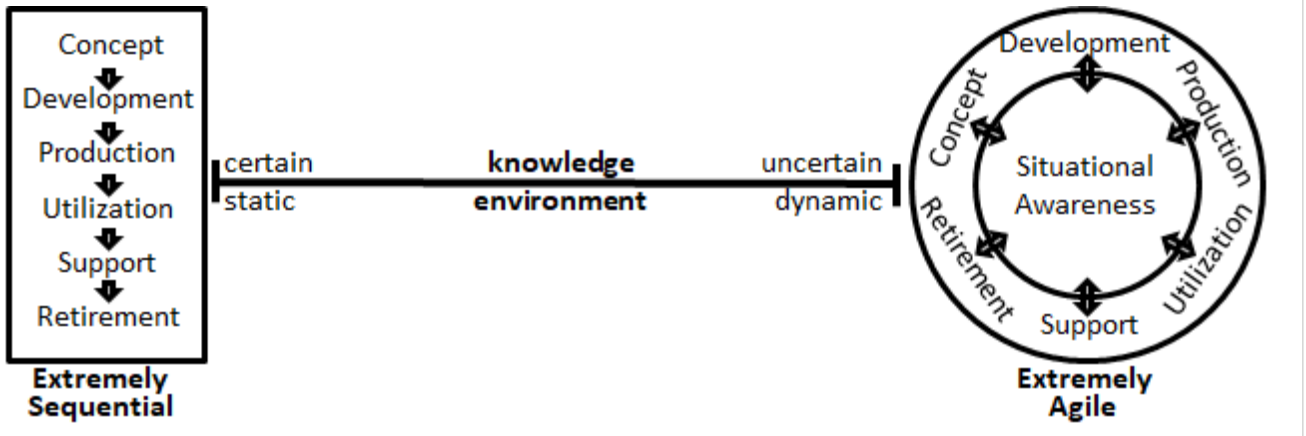

Figure 1. SE life cycle spectrum. (Dove, 2022. Used with permission. All other rights reserved.)

Background Context

In 1991, the US Department of Defense (Nagel and Dove, 1991) funded a project to investigate what would drive competition in manufacturing enterprises after the then-active scramble to become more Lean manufacturing (a term related to the Toyota Production System (Liker, 2004)) had stabilized. The results of that project used the concept of agility and the word agile as a way to describe how organizations could accommodate the increasing frequency of change in markets and technologies. Over the next four years, the Agility Forum, funded by DARPA (Defense Advanced Research Agency) at Lehigh University, led 1200 participants from 125 organizations through a collaborative discovery process across a broad base of business and engineering areas (Dove and LaBarge, 2014). The initial focus on agile manufacturing evolved quickly during the early 1990s into agile systems, agile enterprises, and agile command and control. This led in 2001 to the adoption of the word "agile" to describe a variety of new ways to develop software (e.g. agile software development) (Fowler and Highsmith, 2001). In 2014, INCOSE established "agile systems engineering" as one of its top priorities (Dove and Schindel 2019).

Guidelines for SE Agility

Eight core aspects (Dove et al, 2023, ISO/IEC/IEEE 24748-10) are each explained succinctly as a Why (need) and a What (behavior), with some examples of How (method). Though these aspects are core strategies for any kind of agile engineering, the purpose and descriptions here are for application at the systems engineering level rather than the domain engineering level.

Each of the aspects can individually improve capability to deal with uncertain knowledge and dynamic environments in any engineering process; but to have something intended as an agile engineering process at either domain or system level requires multiple aspects operating in concert. Individual aspects are strategic concepts that can tactically manifest over a range of intensity. Thus, the degree of agility is a product of how many of these aspects are operational as well as how effectively each one contributes to the agility required by the operating environment. Big bang concurrent implementation of all aspects is not necessary to gain agility benefits.

The eight strategic aspects (Dove et al, 2023, ISO/IEC/IEEE 24748-10) of SE agility are:

- adaptable modular architecture
- iterative incremental development
- attentive situational awareness
- attentive decision making
- common-mission teaming
- shared-knowledge management
- continual integration and test
- being agile: operations concept

Adaptable Modular Architectures

Needs: Facilitated product and process experimentation, modification, and evolution.

Behaviors: Composable and reconfigurable product and process designs from variations of reusable assets.

Discussion: One fixed process approach won't fit all projects, so an appropriate process should be easy to compose and evolve according to context and usage experience. Variations of reusable assets are built over time as features are modified for different contextual usage.

A hallmark of agile systems engineering is iterative incremental development, which modifies work in process as suitability is repetitively evaluated. The agility of the process depends upon the agility of the product so both process and product can be easily changed.

Iterative Incremental Development

Needs: Minimize rework, maximize quality, facilitate innovation.

Behaviors: Incremental loops of building, evaluating, correcting, and improving capabilities.

Discussion: Generally, increments create capabilities and iterations add and augment features to improve capabilities.

- Increment cycles are beneficially timed to coordinate events such as integrated testing and evaluation, capability deployment, experimental deployment, or release to production.
- Increments may have constant or variable cadence to accommodate management standards or operational dynamics.
- Iteration cycles are beneficially timed to minimize rework cost as a project learns experimentally and empirically.

Attentive Situational Awareness

Needs: Timely knowledge of emergent risks and opportunities.

Behaviors: Active monitoring and evaluation of relevant internal and external operational environmental factors.

Discussion: Are things being done right (internal awareness) and are the right things being done (external awareness)? Having the agile capability for timely and cost-effective change does little good if you don't know when that ability should be exercised. Situational awareness can be enhanced with systemic methods and mechanisms.

Attentive Decision Making

Needs: Timely corrective and improvement actions.

Behaviors: Systemic linkage of situational awareness to decisive action.

Discussion: Empower decision making at the point of most knowledge. As a counter example, technical debt (a term for knowing something needs correction or improvement but postponing action) is situational awareness without a causal link to prompt action.

Common-Mission Teaming

Needs: Coherent collective pursuit of a common mission.

Behaviors: Engaged collaboration, cooperation, and teaming among all relevant stakeholders.

Discussion: Collaboration, cooperation, and teaming are not synonymous, and need individual support attention. Collaboration is an act of relevant information exchange among individuals, cooperation is an act of optimal give and take among individuals, and teaming is an act of collective endeavor toward a common purpose.

Continual Integration & Test

Needs: Early revelation of system integration issues.

Behaviors: Integrated test and demonstration of work-in-process.

Discussion: Discovering integration issues late in development activities can impact cost and schedule with major rework. Synchronizing multiple domain engineering activities via continual integration and test provides faster and clearer insight into potential system integration issues.

Shared-Knowledge Management

Needs: Accelerated mutual learning and single source of truth for internal and external stakeholders.

Behaviors: Facilitated communication, collaboration, and knowledge curation.

Discussion: There are two kinds of knowledge to consider. Short time frame operational knowledge: what happened, what's happening, what's planned to happen. Long time frame curated knowledge: what do we know of reusable relevance, e.g., digital artifacts, lessons learned, and proven practices.

Being Agile

Needs: Attentive operational response to evolving knowledge and dynamic environments.

Behaviors: Sensing, responding, evolving.

Discussion: Agile systems engineering is not about doing Agile, it is about being agile. Being agile is a behavior, not a procedure—a behavior sensitive to threats and opportunities in the operational environment, decisive when faced with threat or opportunity, and driven to improve these capabilities. Deciding how to implement any of the core aspects, even this one, should be done with sense-respond-evolve principles in mind as aspect objectives.

Industrial DevOps

- Lead Authors:
- Suzette Johnson and Robin Yeman

-

Industrial DevOps (IDO) extends Lean, Agile, and DevOps principles to the design, development, deployment, and sustainment of cyber-physical systems (CPS). As industries face increasing demands for faster delivery, greater resilience, and digital transformation, IDO offers a framework to improve collaboration, accelerate integration, and reduce risk in complex systems. This article synthesizes insights from practical implementations, principles, and advancements, including AI-enabled digital twins, to illustrate how organizations can build better systems faster.

Concepts

DevOps (development and operations) is a set of principles and practices which enable better communication and collaboration between relevant stakeholders for the purpose of specifying, developing, and operating software and systems, products and services, and continuous improvements in all aspects of the life cycle. (See ISO/IEC/IEEE 32675). Industrial DevOps applies lean, agile and DevOps principles to cyber-physical systems throughout their life cycles. Both are potential approaches to address the strategic aspects of SE agility.

Principles

The principles of Industrial DevOps and their associated benefits are outlined below in Table 1.

Industrial DevOps Principles (SEBoK Original)

Principle	Description	Benefit
1. Organize Around the Flow of Value	Organizing cross functionally around the product delivery value stream.	Reduces handoffs between organizations improving communication and delivery speed.
2. Apply Multiple Horizons of Planning	Links the short-term plans to long-term plans using regular business rhythms to adjust long-term plan based on empirical data.	Increase delivery predictability and reduce risk.
3. Implement Data-Driven Decisions	Use current observations and metrics to determine the state, manage the flow of work across systems of systems.	Increase transparency into product scope, schedule, cost and quality.
4. Architect for Change and Speed	Modular components with standardized interfaces.	Rapidly adapts to change. reducing the lead time and impact of change.
5. Manage Queues and Create Flow	Minimize work in progress and focus on smaller batch sizes.	Reduce bottlenecks and Increase delivery speed.
6. Establish Cadence /Synchronization	Put all teams and their work on the same synchronized cadence.	Enables shorter integration loops resulting in risk reduction.
7. Integrate Early and Often	Integrate products and resources using frequent integration points.	Faster feedback cycles and reduced risk.

8. Shift Left	Shifting left emphasizes a “test-first” mindset encompassing the multiple levels of testing across cyber-physical systems.	Reduced rework, built in quality resulting in increased delivery speed.
9. Adopt a Growth Mindset	Applying a growth mindset expresses the need to continuously learn.	Increased quality and innovation.

Enabling practices

The enabling practices of Industrial DevOps (IDO) shown in the bulleted list below translate its core principles into actionable strategies that drive real-world implementation across complex, cyber-physical systems. These practices support the seamless integration of hardware and software development, enabling organizations to respond more rapidly to change, reduce delivery risk, and enhance product quality throughout the system lifecycle. As industrial systems face increasing demands for speed, adaptability, and resilience, these practices help bridge traditional silos between engineering disciplines, streamline workflows, and foster a culture of continuous improvement.

From value stream management and test automation to the use of AI-enabled digital twins and infrastructure as code, these practices offer the tools and methods necessary to operationalize IDO. They not only improve technical execution but also support organizational transformation by aligning teams, automating compliance, and promoting agile program execution. Together, they form a foundation that empowers industrial enterprises to build better systems faster while maintaining the rigor and reliability required in high-stakes environments.

- **Value Stream Management** - Enables visualization and optimization of work from concept to deployment. It helps identify delays, waste, and inefficiencies across the full value stream.
- **Integrated Digital Engineering (IDE)** - Leverages digital models and simulations (such as digital twins) to support continuous integration and validation of both hardware and software systems.
- **Agile Program Execution** - Focuses on aligning multiple teams through program increment planning, system demos, and synchronized cadences to deliver value effectively and predictably.
- **Test Automation and Virtualization** - Includes test-first approaches, automated testing, and use of virtual environments to verify functionality early and continuously throughout the development cycle.
- **Continuous Integration and Deployment (CI/CD)** - Enables teams to integrate, test, and release updates rapidly and safely, even in complex, safety-critical environments.
- **Infrastructure as Code (IaC)** - Uses code to manage and provision hardware and software infrastructure, enabling repeatable and reliable deployments.
- **AI and Digital Twins** - Supports predictive maintenance, performance optimization, and real-time decision-making by simulating the behavior of physical systems through digital replicas.
- **Lean Governance and Compliance Automation** - Applies automation and lean thinking to ensure that governance, regulatory, and security requirements are met without slowing delivery.

Selecting the Life Cycle Model

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Life cycle models serve as essential frameworks that guide the development and management of systems and services throughout their existence. Adapted to organizational needs, these models help align projects with strategic goals while accommodating industry regulations and internal diversity. Far from being static, effective life cycle models evolve through continuous improvement and performance measurement. They enable consistent project execution, facilitate knowledge sharing, and support efficient resource use. Creating the right model requires balancing regulatory demands with best practices and corporate culture, ensuring relevance and stakeholder commitment. Sustained success depends on regularly reviewing and adapting these models to changing conditions.

Align to 24748-1, 6.2.6

Concepts

A life cycle model is a framework of processes and activities concerned with the life cycle which can be organized into stages, acting as a common reference for communication and understanding [SOURCE: ISO/IEC/IEEE 24748-1:2024]. Decision-making reviews or gates based on specific entry or exit criteria are typically part of a life cycle model. Organizations create and maintain life cycle models to develop systems or services that meet their strategic plans, policies, goals and objectives.

Life cycle models should always be organization-specific, even if there are regulatory requirements regarding the life cycle model in certain industries. Creating a life cycle model is one of the biggest challenges for organizations, as it is often the case that a large number of very different projects have to be managed. These differences can be due to the size of the project, the degree of complexity, the proportion of new technologies, customer requirements, or approval regulations when entering new business areas, for example. Accordingly, it can happen that organizations develop several alternative life cycle models and draw up instructions as to which one is to be used in which cases and what adaptation may be needed.

The selected life cycle models should not be seen as rigid constructs. On the one hand, they are adapted to the project-specific requirements for each project and, on the other, periodic reviews should take place to check whether the current life cycle models are still up-to-date and appropriate. The life cycle models are therefore subject to continuous evaluation and improvement, which must keep pace with the speed at which the organization or customer requirements change. For this reason, it is advisable to develop key performance indicators together with the life cycle models that make it possible to measure efficiency and effectiveness in meeting requirements. These key performance indicators should then also be used to continuously improve the life cycle models and associated planning.

Value proposition

The introduction of company-wide processes has many advantages. The associated value propositions are [SOURCE: INCOSE SEHv5, 7.1.1.1]

- Provide repeatable/predictable performance across the projects in the organization (this helps the organization in planning and estimating future projects and in demonstrating reliability to stakeholders)
- Leverage practices that have been proven successful by certain projects and instill those in other projects across the organization (where applicable)
- Enable process improvement across the organization
- Improve ability to efficiently transfer staff across projects as roles are defined and performed consistently
- Enable leveraging lessons that are learned from one project for future projects to improve performance and avoid issues
- Improve startup of new projects (less reinventing the wheel)

Additional benefits can be generated through the use of shared resources (e.g., tool support, document templates, knowledge management database).

Establish life cycle models

The life cycle models created by organizations are usually based on the following inputs:

- Legislative, regulatory, and other government requirements
- Industry SE and management-related standards, training, and capability maturity models
- Academic education, research results, future concepts and perspectives, and requests for financial support

Every organization would do well to create its own life cycle models. Since every organization is unique in terms of its industry, history and culture, the life cycle models should reflect this. Experience shows that life cycle models that work excellently in one organization cannot easily be transferred to other organizations.

In order to create the “right” life cycle models, all relevant stakeholders should be involved. This increases their commitment to the rules created and prevents the not-invented-here syndrome.

The creation of suitable life cycle models is therefore always a balancing act between regulatory requirements, appropriate best practices and the corporate culture or company history.

Maintain life cycle models

As the input variables for selected life cycle models are constantly changing, it is advisable to constantly monitor developments in relation to the inputs listed under “Establish life cycle models” above.

Adapting the Life Cycle Model

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Adapting a life cycle model to suit a specific project requires thoughtful consideration of both system scope, organizational context, and customer requirements. Modifying stages, criteria, or reviews can help tailor the model to unique needs, but such changes must be guided, documented, and often approved to maintain alignment with organizational standards. Adaptation must also account for multi-party collaborations, where responsibilities shift across different life cycle phases. Additionally, differing domains like hardware and software may call for distinct, but synchronized models. To ensure coherence and efficiency, customized approaches must be selected for each stage (i.e., development through retirement) based on the project's technical and operational demands.

Adaptation of the Model and Stages for Scope

Once an appropriate life cycle model has been selected, it can be adapted to meet the specific needs of the project and system. These specific needs can originate both inside (e.g., product line considerations, follow-on business) and outside (e.g., regulations, customer requirements or preferences) the organization. When adapting a life cycle model, it is important to consider the overall scope. If other projects carried out in the same organization are ignored, some of the value propositions listed in Article “Article – Selecting the Life Cycle Model” may no longer be fulfilled.

When adapting a life cycle model, stages can be added, deleted, combined, or modified as appropriate. Adaption guidelines are usually developed together with the life cycle models, which specify the extent to which life cycle models may be adapted. As soon as these limits are exceeded, it is necessary for these adaptations to be approved by the organization. In general, all adaptations must be documented. Adaption also includes any changes to entry or exit criteria of the reviews or audits to facilitate transitions between stages.

A case could be that organization X buys a concept from organization A, then establishes a project to develop the system, then outsources the production to organization B, then sells the system to organization C, which is responsible for operation and maintenance, and in the end is itself responsible for the disposal of the system. In this case, organization X is responsible for the life cycle stages for development and retirement. At the same time, the transitions to the other life cycle stages must be considered as well.

Adaptation for domains

A life cycle model appropriate for a software system might be different from the life cycle model appropriate for a system dominated by hardware. It is not necessary that the software uses a life cycle appropriate for the hardware, nor is it necessary for the hardware to use a life cycle appropriate for the software. A system that has both hardware and software elements could have a combination of life cycle models, synchronized at certain points. Life cycle models should be adapted based on the domains involved. Each domain's perspective on the system element's life cycle should be considered.

Selection and Adaptation of Approaches for all Stages of the Life Cycle

Regardless of the life cycle model, each of the life cycle stages needs to have an approach selected and adapted to the context of the system and project. Systems engineers will be familiar with the need to select and adapt a development approach for the system. Note that the development approach can be different for different elements of the system. In addition, approaches need to be selected and adapted for the other life cycle stages: production, utilization, support, and retirement. Planning for these should be documented.

Selecting the Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Choosing the right development approach is a critical step after selecting and adapting a life cycle model. Each system element or enabling system may require its own approach, especially in complex or innovative projects involving new technologies or business domains. Options like sequential, incremental, evolutionary, or agile must be weighed based on risk, system size, requirements clarity, and other contextual factors. Tools such as risk analysis and frameworks like PMI's Situation Context Framework offer valuable guidance. A shared understanding between acquirer and supplier is essential to ensure alignment on strategy, resources, and delivery expectations throughout the system's development.

Select the Development Approach

Within the selected life cycle model for the system of interest, and after that model has been adapted as appropriate, the specifics of the development approach for the system of interest should be selected and adapted. Determination of the development approach should be performed not just for the system of interest, but for each system element, as well as each enabling system. It is possible, perhaps likely, that the development approaches will differ.

A particular challenge arises when the system of interest involves new technologies or is developed to target a new business area. It is then very likely that development approaches used previously are no longer up-to-date and applicable.

Candidate development approaches include Sequential, Incremental, Evolutionary, and Agile. Depending on what is known and what is not known, a development approach can be more favorable in terms of reducing risk. Risk analysis can be used to compare the development approaches to help guide the selection process.

There are good practices on how to select a suitable development approach, for example in ISO/IEC/IEEE 24748-1. The Project Management Institute (PMI) published their Situation Context Framework (SCF) [1] that "defines how to select and tailor a situation-dependent strategy for software development. The SCF is used to provide context for organizing your people, process, and tools for a software-based solution delivery team." This framework defines seven dimensions (team size, geographic distribution, organizational distribution, skill availability, compliance, domain complexity, and solution complexity) with scaling factors in each dimension.

Considerations:

- How well are the requirements understood
- How large is the system
- How quickly is technology changing
- How constrained is the staff
- How constrained is the budget
- Does the user have preferences on capabilities in first delivery
- Does the user need to phase out an old system at once

There should be agreement between the acquirer and supplier on the development approaches.

Adapting the Development Approach

- Lead Author:
- David Endler
- Contributing Authors:
- Mike Yokell and Garry Roedler

-

Adapting development approaches to suit the unique demands of each project is essential for success, especially when facing new technologies, diverse system elements, or changing business strategies. As projects grow more complex, with components spanning different domains like software and hardware, coordinated development becomes increasingly important. Aligning development cycles, managing interface consistency, and considering domain-specific requirements all influence how approaches are adapted. Additionally, certain quality characteristics such as stealth in military systems or safety in healthcare demand further refinement of the development process. Thoughtful adaptation, led by experienced systems engineers, ensures development strategies remain fit for purpose in diverse and evolving contexts.

Adaptation of the Development Approach

Since every project is unique, in most cases it is necessary to adapt not only the life cycle model but also the development approach to the project-specific circumstances. There can be many reasons for this adaptation. For example, if for the organization previously unknown technologies are to be implemented, the approaches used so far are probably no longer up to date. It is also possible that the system elements are very different from one another in terms of their domain characteristics (e.g. software-intensive vs. purely mechanical). Another reason could be that the project is taking a different approach to make or buy than in previous projects.

Adaptation for domains

For larger, complex systems in particular, different development approaches may be used for different system elements. If these development approaches are then also adapted, it is extremely important that the development results of the individual system elements are regularly aligned with each other. These intervals should not be too short. For example, if the software team develops a new release within two weeks, it is unlikely that the associated hardware will have undergone major changes in the same period. At the same time, the intervals should not be too long, as design decisions may then be made without taking other domains into account. As a consequence, there will be inconsistencies at the interfaces that are difficult to resolve.

In most cases, it is the task of experienced systems engineers to adapt the development approaches. In order to come to an educated decision, it is advisable to involve those responsible for the individual system elements. This encourages buy-in from everyone involved and ensures that as many opinions and concerns as possible have been taken into account.

Adaptation for quality characteristics

Some system developments are dominated by certain quality characteristics. For example, when designing a military submarine, it is extremely important that its signature is kept to an absolute minimum. In healthcare projects, topics like system safety and security are usually of particular importance.

In such cases, the development approaches for the system or some of its system elements may have to be adapted to take these peculiarities into account. In the example of the military submarine, it is important that the individual system elements are well coordinated. The reason for this is that even small effects can build up as soon as system elements are integrated into larger assemblies or the overall system of interest. The development approach must therefore aim to ensure that the exchange between the individual departments that develop the system elements functions as smoothly as possible.

In healthcare projects, not only the end product but also the process to it is closely examined by the responsible authorities. The focus in such projects is therefore on predictability, stability, repeatability, and high assurance. All these are characteristics of sequential development approaches.

Applying Life Cycle Processes

- Lead Author:
- Rick Adcock

-

The Generic Life Cycle Model describes a set of life cycle stages and their relationships. In defining this we described some of the technical and management activities critical to the success of each stage. While this association of activity to stage is important, we must also recognize the through life relationships between these activities to ensure we take a systems approach.

Systems Engineering technical and management activities are defined in a set of life cycle processes. These group together closely related activities and allow us to describe the relationships between them. In this topic, we discuss a number of views on the nature of the inter-relationships between process activities within a life cycle model.

In general, the technical and management activities are applied in accordance with the principles of concurrency, iteration and recursion described in the generic systems engineering paradigm. These principles overlap to some extent and can be seen as related views of the same fundamental need to ensure we can take a holistic systems approach, while allowing for some structuring and sequence of our activities. The views presented below should be seen as examples of the ways in which different SE authors present these overlapping ideas.

Life Cycle Process Terminology

Process

A process is a series of actions or steps taken in order to achieve a particular end. Processes can be performed by humans or machines transforming inputs into outputs.

In the SEBoK, processes are interpreted in several ways, including: technical, life cycle, business, or manufacturing flow processes. Many of the Part 3 sections are structured along technical processes (e.g. design, verification); however, Life Cycle Models also describes a number of high-level program life cycle sequence which call themselves processes (e.g. rational unified process (RUP), etc.).

Part 4: Applications of Systems Engineering and Part 5: Enabling Systems Engineering utilize processes that are related to services and business enterprise operations.

Systems Engineering life cycle processes define technical and management activities performed across one or more stages to provide the information needed to make life cycle decisions; and to enable realization, use and sustainment of a system-of-interest (SoI) across its life cycle model as necessary. This relationship between life cycle models and process activities can be used to describe how SE is applied to different system contexts.

Requirement

A requirement is something that is needed or wanted but may not be compulsory in all circumstances. Requirements may refer to product or process characteristics or constraints. Different understandings of requirements are dependent upon process state, level of abstraction, and type (e.g. functional, performance, constraint). An individual requirement may also have multiple interpretations over time.

Requirements exist at multiple levels of enterprise or systems with multiple levels of abstraction. This ranges from the highest level of the enterprise capability or customer need to the lowest level of the system design. Thus, requirements need to be defined at the appropriate level of detail for the level of the entity to which they apply. See the articles System Concept Definition and System Requirements Definition for further detail on the transformation of needs and requirements from the enterprise to the lowest system element across concept definition and system

definition.

Architecture

An architecture refers to the organizational structure of a system, whereby the system can be defined in different contexts. Architecting is the art or practice of designing the structures. See below for further discussions on the use of levels of Logical and Physical architecture models to define related system and system elements; and support the requirements activities.

Architectures can apply for a system product, enterprise, or service. For example, Part 3 mostly considers product or service related architectures that systems engineers create, but enterprise architecture describes the structure of an organization. Part 5: Enabling Systems Engineering interprets enterprise architecture in a much broader manner than an IT system used across an organization, which is a specific instance of architecture.

Frameworks are closely related to architectures, as they are ways of representing architectures. See Architecture Framework for definition and examples.

Other Processes

A number of other life cycle processes are mentioned below, including system analysis, integration, verification, validation, deployment, operation, maintenance and disposal; they are discussed in detail in the System Realization and System Deployment and Use knowledge areas.

Life Cycle Process Concurrency

In the Generic Life Cycle Model, we have listed key activities critical to successful completion of each stage. This is a useful way to illustrate the goals of each stage and gives an indication of how processes align with these stages. This can be important when considering how to plan for resources, milestones, etc. However, it is important to observe that the execution of process activities is not compartmentalized to particular life cycle stages (Lawson 2010).

Figure 1 shows a simple illustration of the through life nature of technical and management processes. This figure builds directly on the "hump diagram" principles described in Systems Approach Applied to Engineered Systems.

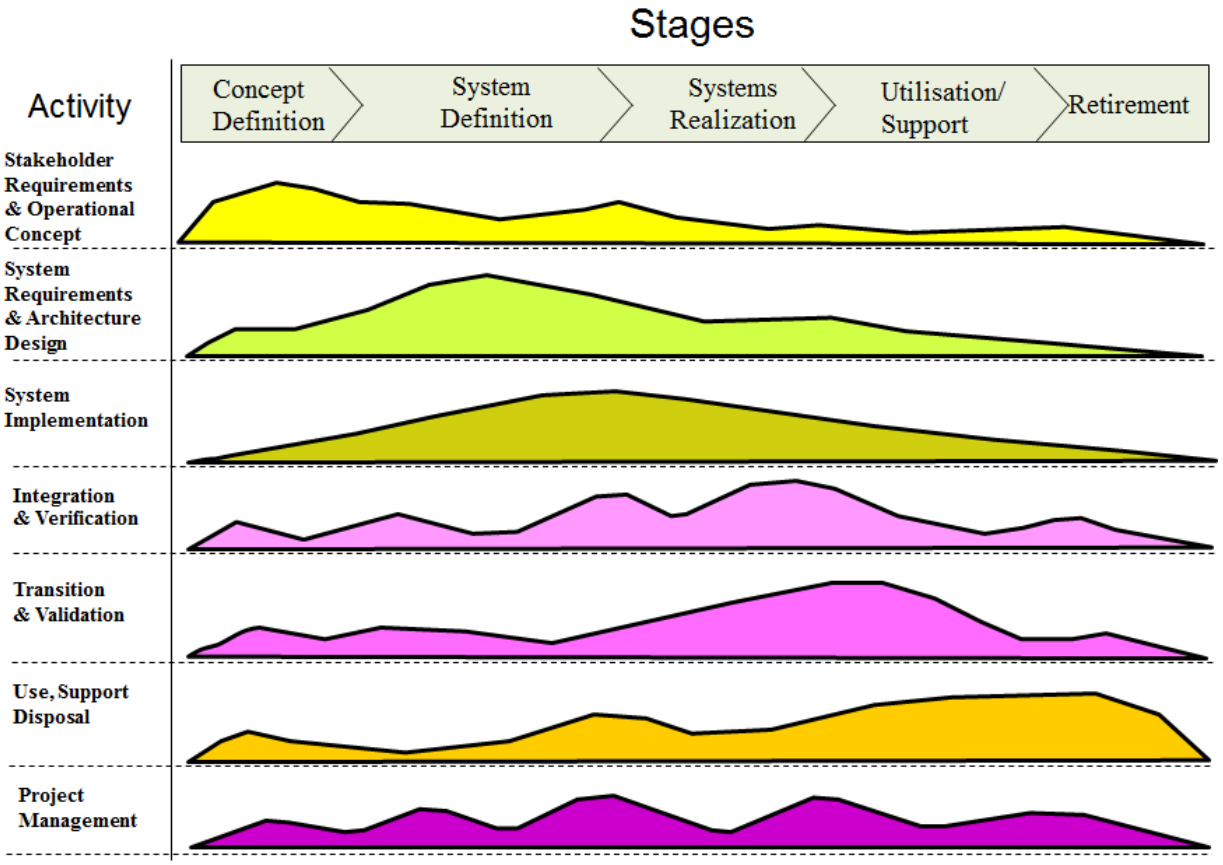

Figure 1: Generic Relationships between life cycle stages and processes (modified from Lawson 2010)

The lines on this diagram represent the amount of activity for each process over the generic life cycle. The peaks (or humps) of activity represent the periods when a process activity becomes the main focus of a stage. The activity before and after these peaks may represent through life issues raised by a process focus, e.g. how likely maintenance constraints will be represented in the system requirements. These considerations help maintain a more holistic perspective in each stage, or they can represent forward planning to ensure the resources needed to complete future activities have been included in estimates and plans, e.g. all resources needed for verification are in place or available. Ensuring this hump diagram principle is implemented in a way which is achievable, affordable and appropriate to the situation is a critical driver for all life cycle models.

Life Cycle Process Iteration

The concept of iteration applies to life cycle stages within a life cycle model, and also applies to processes. Figure 2 below gives an example of iteration in the life cycle processes associated with concept and system definition.

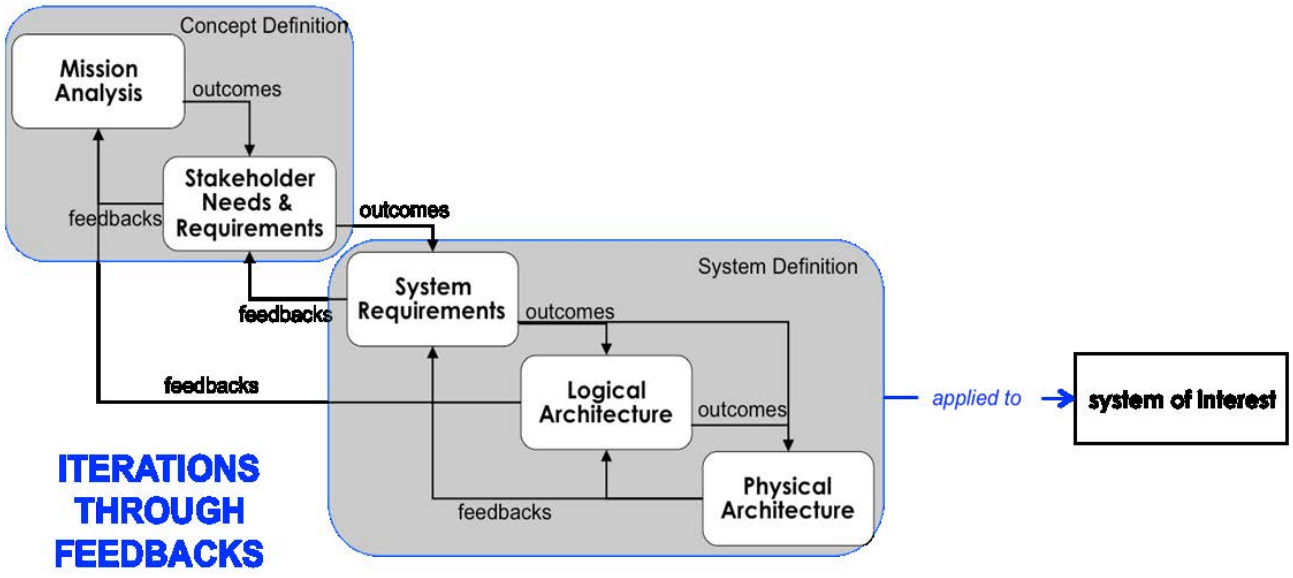

Figure 2. Example of Iterations of Processes Related to System Definition (Faisandier 2012). Permission Granted by Sinergy'Com. All other rights are reserved by the copyright owner.

There is generally a close coupling between the exploration of a problem or opportunity and the definition of one or more feasible solutions; see Systems Approach to Engineered Systems. Thus, the related processes in this example will normally be applied in an iterative way. The relationships between these processes are further discussed in the System Definition KA.

Figure 3 below gives an example of the iteration between the other life cycle processes.

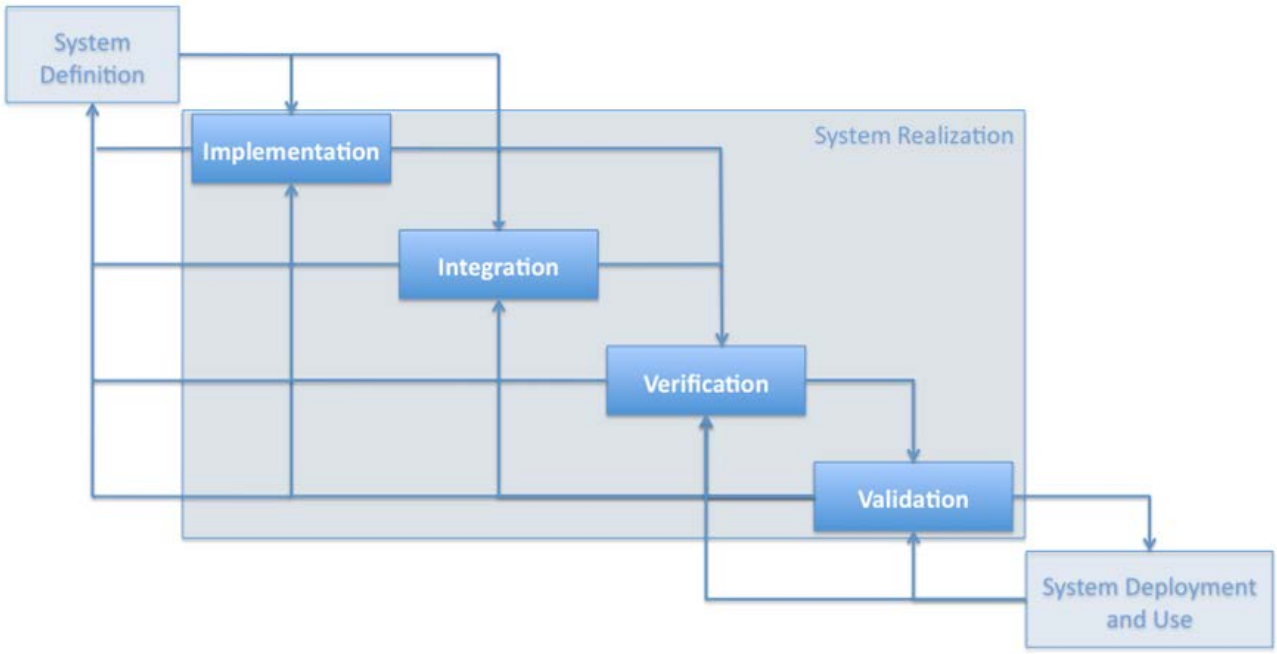

Figure 3. System Realization. (SEBoK Original)

The iterations in this example relate to the overlaps in process outcomes shown in Figure 1. They either allow consideration of cross process issues to influence the system definition (e.g. considering likely integration or verification approaches might make us think about failure modes or add data collection or monitoring elements into the system) or they allow risk management and through life planning activities to identify the need for future activities.

The relationships between these processes are further discussed in system realization and system deployment and use.

Life Cycle Process Recursion

The comprehensive definition of a SoI is generally achieved using decomposition layers and system elements. Figure 4 presents a fundamental schema of a system breakdown structure.

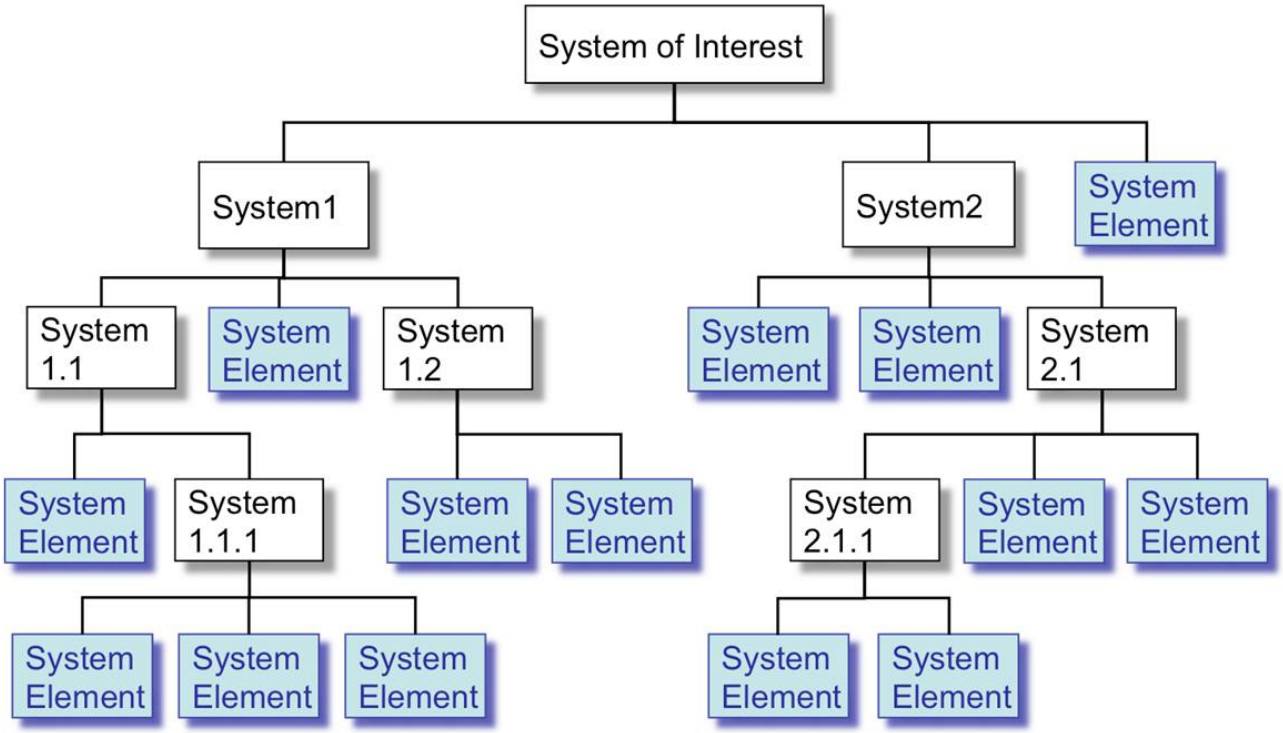

Figure 4. Hierarchical Decomposition of a System-of-Interest (Faisandier 2012). Permission Granted by Sinergy'Com. All other rights are reserved by the copyright owner.

In each decomposition layer and for each system, the System Definition processes are applied recursively because the notion of "system" is in itself recursive; the notions of SoI, system, and system element are based on the same concepts (see Part 2). Figure 5 shows an example of the recursion of life cycle processes.

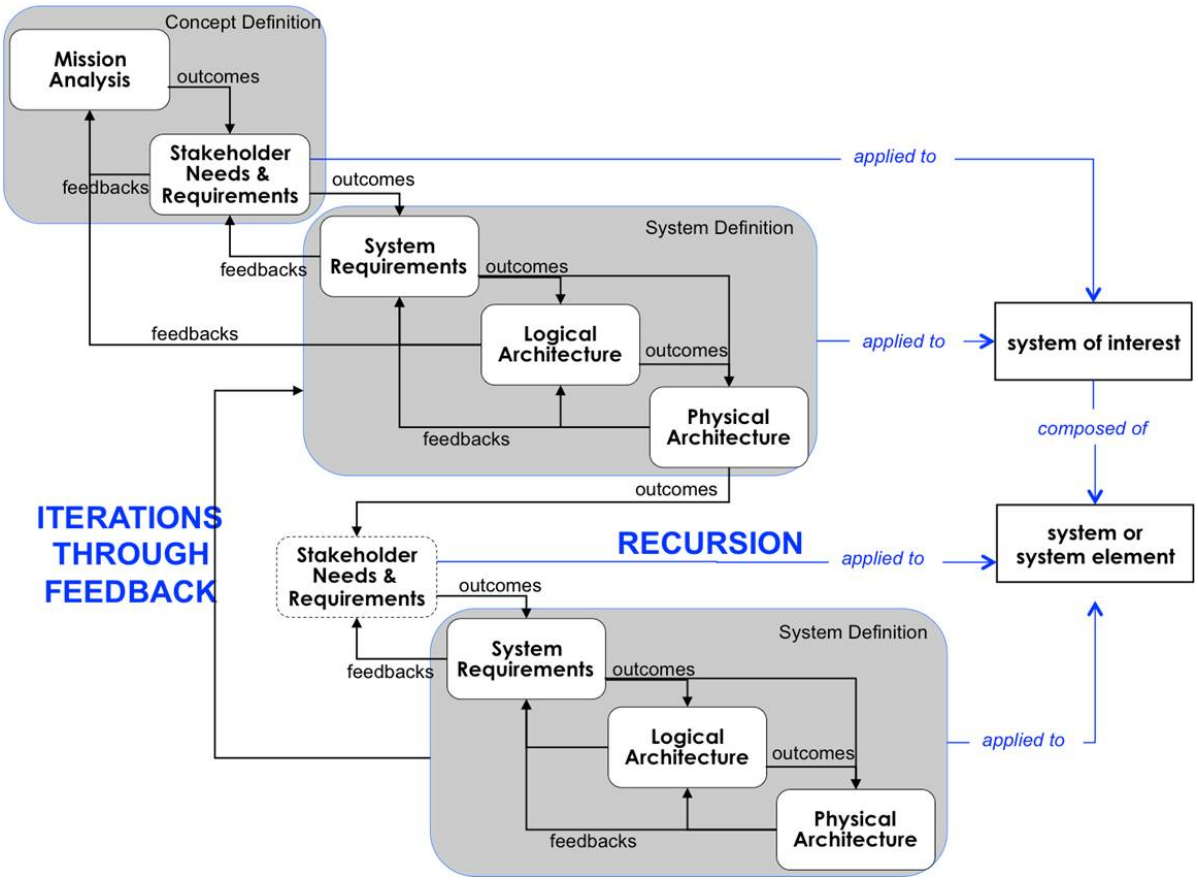

Figure 5. Recursion of Processes on Layers (Faisandier 2012). Permission Granted by Sinergy'Com. All other rights are reserved by the copyright owner.

Systems Approach to Solution Synthesis

The sections above give different perspectives on how SE life cycle processes are related and how this shapes their application. Solution synthesis is described in Part 2 as a way of taking a systems approach to creating solutions. Synthesis is, in general, a mixture of top-down and bottom-up approaches as discussed below.

Top-Down Approach: From Problem to Solution

In a top-down approach, concept definition activities are focused primarily on understanding the problem, the operational needs/requirements within the problem space, and the conditions that constrain the solution and bound the solution space. The concept definition activities determine the mission context, mission analysis, and the needs to be fulfilled in that context by a new or modified system (i.e. the SoI), and address stakeholder needs and requirements.

The system definition activities consider functional, behavioral, temporal, and physical aspects of one or more solutions based on the results of concept definition. System analysis considers the advantages and disadvantages of the proposed system solutions both in terms of how they satisfy the needs established in concept definition, as well as the relative cost, time scales and other development issues. This may require further refinement of the concept definition to ensure all legacy relationships and stakeholders relevant to a particular solution architecture have been considered in the stakeholder requirements.

The outcomes of this iteration between Concept Definition and System Definition define a required system solution and its associated problem context, which are used for System Realization, System Deployment and Use, and Product and Service Life Management of one or more solution implementations. In this approach, problem

understanding and solution selection activities are completed in the front-end portion of system development and design and then maintained and refined as necessary throughout the life cycle of any resulting solution systems. Top-down activities can be sequential, iterative, recursive or evolutionary depending upon the life cycle model.

Bottom-Up Approach: Evolution of the Solution

In some situations, the concept definition activities determine the need to evolve existing capabilities or add new capabilities to an existing system. During the concept definition, the alternatives to address the needs are evaluated. Engineers are then led to reconsider the system definition in order to modify or adapt some structural, functional, behavioral, or temporal properties during the product or service life cycle for a changing context of use or for the purpose of improving existing solutions.

Reverse engineering is often necessary to enable system engineers to (re)characterize the properties of the system-of-interest (SoI) or its elements. This is an important step to ensure that system engineers understand the SoI before beginning modification. For more information on system definition, see the System Definition article.

A bottom-up approach is necessary for analysis purposes, or for (re)using existing elements in the design architecture. Changes in the context of use or a need for improvement can prompt this. In contrast, a top-down approach is generally used to define an initial design solution corresponding to a problem or a set of needs.

Solution Synthesis

In most real problems, a combination of bottom-up and top-down approaches provides the right mixture of innovative solution thinking driven by need, and constrained and pragmatic thinking driven by what already exists. This is often referred to as a "middle-out" approach.

As well as being the most pragmatic approach, synthesis has the potential to keep the life cycle focused on whole system issues, while allowing the exploration of the focused levels of detail needed to describe realizable solutions; see Synthesising System Solutions for more information.

Systems engineering relies on a well-defined set of processes that guide the development of complex systems along the whole life cycle. These processes form the backbone of systematic engineering practice, differentiating it from ad-hoc approaches. ISO/IEC/IEEE 24774 standardizes process descriptions to ensure clarity, consistency, and comparability. However, they are not meant to be executed in a serial, sequential fashion. Concurrency, iteration, and recursion ensure dynamic, non-linear system life cycle management.

Process Description

- Lead Author:
- David Endler
- Contributing Author:
- Mike Yokell

-

A life cycle model provides a framework of processes and activities guiding a system's life cycle. ISO/IEC/IEEE 24774 standardizes process descriptions to ensure clarity, consistency, and comparability. Each process includes a name, purpose, and outcomes, with optional activities, tasks, inputs, and outputs. Consistent descriptions enhance understanding, compliance, and improvement, supporting systematic, transparent, and adaptable system engineering practices.

Fundamental Concepts

Article Life Cycle Models describes that a life cycle model is a framework of processes and activities concerned with the life cycle. Processes and activities that are integrated into the framework of a life cycle model are often referred to as life cycle processes.

The purpose of ISO/IEC/IEEE 24774, *Specification for process description,* (available for free at: https://www.iso.org/standard/78981.html) is to *"encourage uniformity in the description of processes"*. This international standard specifies the way process descriptions should be established and builds on the lessons learned from other international, national, and industry standards that describe processes and process models.

Defining processes in a consistent manner ensures that they are understandable, comparable, and manageable. Consistency provides a common language for describing how work is done, which reduces ambiguity and simplifies collaboration. It enables alignment with standards, regulations, and good practices, ensuring that processes are not only efficient but also compliant. When processes follow a consistent structure, it becomes easier to document, analyze, and improve them systematically. This also supports training and knowledge transfer, as users can quickly grasp and apply established methods.

Processes can be specified using the following elements (ISO/IEC/IEEE 24774):

Table 1. Process Elements. (SEBoK Original)

	Required Element	Optional Elements	For Any Other Element
Process	Name	Inputs	Notes
	Purpose	Activities	Controls
	Outcomes	Tasks	Constraints
		Outputs	

According to ISO/IEC/IEEE 24774, at a minimum, process descriptions include the elements **Name, Purpose, and Outcomes**. Additional details, such as inputs, outputs, activities, or tasks, can be added if needed but are not mandatory. The core elements capture the goals and objectives of the process, focusing on the intended results without requiring a detailed structural breakdown. By defining processes in terms of Name, Purpose, and Outcomes, organizations establish a clear and consistent foundation. This approach ensures that processes can be easily understood, implemented, and assessed, while still allowing for further elaboration if deeper analysis or refinement becomes necessary.

Elements of Process Description

Process Name (Required)

The name of a process should be a concise noun phrase that clearly identifies its main focus and distinguishes it from other processes. Verbs should be avoided because they can lead to situations where the process name resembles activities or purposes.

Process Purpose (Required)

The purpose of a process should express one or more high-level goals that define why the process is performed. It helps clarify the scope and boundaries, especially when processes appear to overlap. Ideally, the purpose is stated in a single, concise sentence, beginning with *"The purpose of the xxx process is..."*. It should not summarize activities or outcomes, and the use of "and" should be avoided to prevent listing unrelated goals. Additional context or explanations can be provided separately in notes or supporting text.

Process Outcomes (Required)

Process outcomes represent measurable and observable results or change of state achieved by executing a process. Unlike outputs, they are not defined as documents, records, or information items, but rather as tangible technical or business achievements. Each outcome should be written as a single, present-tense declarative sentence, expressing a clear, positive objective such as delivering a service, achieving a change of state, maintaining a desired condition, or meeting defined requirements. To ensure clarity, outcomes should avoid conjunctions like *"and"* or *"and/or",* separate statements should be used instead. Typically, a process should have three to seven concise outcomes, each directly supporting its stated purpose. Outcomes are distinct from benefits, which describe broader organizational gains and can be recorded separately as informative notes.

Process Activities (Optional)

According to ISO/IEC/IEEE 24774, activities are defined as "set of cohesive tasks of a process". Process activities describe the broad actions undertaken to execute a process. They group related tasks (see below) to improve understanding and communication and can, if cohesive and well-defined, be treated as lower-level processes with their own purposes and outcomes. All activities together must achieve the process outcomes and purpose. Activities should be strongly related internally (across its tasks) but loosely connected to other activities. They are not sequential steps but ongoing responsibilities, avoiding imposed timing or order unless explicitly required.

Process Tasks (Optional)

According to ISO/IEC/IEEE 24774, a task is defined as a "required, recommended, or permissible action, intended to contribute to the achievement of one or more outcomes of a process".

Process tasks specify concrete requirements, recommendations, or permissible actions that guide the execution of a process. They are written to support the achievement of process outcomes but do not need to fully cover the scope of an activity. Instead, tasks can be seen as discrete points within the broader space of processes and activities. Additional tasks can be included to clarify conformance requirements or to support higher capability levels. Timing or sequencing should not be assumed unless explicitly stated, ensuring flexibility across different life cycle models.

Process Inputs (Optional)

Process inputs are items that get transformed into outputs through the execution of the process, excluding the human or automated resources that perform the work. Inputs can originate from other processes, organizational resources, suppliers, or external sources. While specifying inputs is optional, it becomes essential in closed-loop life cycles.

Process Outputs (Optional)

Process outputs can be specified in descriptions but are optional if outcomes can be demonstrated. Some outputs are essential deliverables, while others serve only for validation or audit. They are generally categorized as artefacts (e.g., prototypes, models, components, or services) or information items with defined characteristics. Artifacts further include four generic work product types: services, software, hardware, and processed materials.

Process Notes (For Any Other Element)

Process notes contain further information on the what, how and why. In many cases, they explain the interrelationship with other processes and also main contain brief examples.

Process Controls and Constraints

Process controls and process constraints guide or restrict how a process is performed, and to some extent when. Controls can originate from laws, regulations, organizational policies, voluntary standards, or agreements with suppliers and customers. Constraints often stem from external environmental or business conditions. They can be documented in a dedicated section of the process description or included as notes alongside other process elements.

Elaboration

In INCOSE SEHv5 section 2.3 a common structure has been applied to describe the system life cycle processes. To maintain alignment with ISO/IEC/IEEE 15288, the purpose statements from the standard are reproduced verbatim for each process described in INCOSE SEHv5. Similarly, the titles of process activities follow the standard, describing **what** should be done rather than **how** to perform the tasks. Additional elements are included in some cases to summarize industry best practices and recent developments in systems engineering processes. Process elaborations provide further details specific to each life cycle process.

Each system life cycle process is also represented by an input-process-output (IPO) diagram, showing typical inputs, activities, and typical outputs. While the outcomes are included in ISO/IEC/IEEE 15288, they are not included in INCOSE SEHv5. Instead, INCOSE SEHv5 contains typical inputs and outputs for each process.

They can take any form (e.g., database, document, model, etc), and combinations of inputs and outputs in one artifact are also possible. The names of the inputs and outputs can vary depending on domain, company, or project.

In INCOSE SEHv5, controls and enablers are typically excluded from input-process-output (IPO) diagrams, in figure 1 they are noted, showing how inputs are transformed into outputs under process controls.

These diagrams illustrate one possible way to perform the process, not a mandatory approach. Outputs often represent results captured as documents, artifacts, or models, rather than being produced solely because they are listed.

Process Concurrency, Iteration, and Recursion

- Lead Author:
- David Endler
- Contributing Author:
- Mike Yokell

-

Concurrency, iteration, and recursion ensure dynamic, non-linear system life cycle management. Concurrency allows parallel processes; iteration enables refinement through feedback and evolving requirements; recursion applies processes across system levels for consistency. Together, they promote continuous learning, adaptability, and informed decision-making throughout system definition and realization.

Fundamental Concepts

The concepts of concurrency, iteration, and recursion is also discussed in ISO/IEC/IEEE 15288 and article Applying the Systems Approach. While the article in SEBoK Part 2 explains the application of concurrency , iteration, and recursion in the development of complex systems, this article deals with the application of these concepts to life cycle processes.

The system life cycle processes are sometimes mistakenly perceived as linear and sequential, applied at a single system hierarchy level. In reality, effective system life cycle management relies on exchanging information and insights across processes to ensure a system definition that meets stakeholder needs efficiently and effectively. To do this, it is often necessary to account for learning and feedback that is obtained as processes are applied during the system definition. Applying concurrency, iteration, and recursion supports continuous communication, ongoing learning, and informed decision-making as the technical solution evolves.

Concurrency

Concurrency involves performing two or more processes in parallel. Many processes can proceed simultaneously when they do not strongly depend on each other's outputs. For instance, risk management and measurement processes are typically continuous and concurrent.

Iteration

Iteration refers to repeated application and interaction between processes for a variety of reasons, including to accommodate stakeholder decisions, to incorporate learning and feedback, and evolving understanding, architectural constraints, and trade-offs for affordability, feasibility, resilience, and adaptability. Iteration frequently occurs between processes such as system requirements definition and system architecture definition. Evolving requirements can drive architectural changes, which in turn can prompt updates to requirements, design, or trade-offs.

Recursion

Recursion is the repeated application of life cycle processes throughout the system structure. Technical Management and Technical Processes are applied recursively for many reasons, including defining the system at continually lower levels until decisions on make, buy, or reuse are made. Outputs from one element level serve as inputs for another, whether in system definition or system realization, ensuring consistency and integrity.

Guidelines for the Selection and Tailoring of Processes

- Lead Author:
- David Endler
- Contributing Author:
- Mike Yokell

-

Selecting suitable life cycle processes is strategic, requiring flexibility, compliance, and alignment with standards like ISO/IEC/IEEE 24748-2. Key principles include risk-based rigor, tailoring, traceability, tool integration, and governance. Success depends on human factors, learning, reuse, and management support. Effective frameworks balance rigor with agility, using feedback, training, and pilot projects to ensure continuous improvement.

Fundamental Concepts

Selecting appropriate processes for use throughout the life cycle of systems is a strategic challenge for organizations. In many cases, ISO/IEC/IEEE 24748-2 is a useful resource for this challenge. The goal is to create a flexible, adaptable framework that ensures compliance, quality, and efficiency while allowing innovation and agility. This requires aligning with consensus standards, learning from past experience, and tailoring processes to project-specific needs.

Core Principles

When selecting system life cycle processes, consider the following principles:

- Risk and context: Process rigor should match system complexity, criticality, and regulatory environment. For example, a safety-critical avionics system requires more rigorous analysis and stringent verification than a home TV screen.
- Tailoring: Consider tailoring upfront, it will happen. In almost every project, the process framework needs to be tailored to the project-specific context, life cycle model and approach, with documented rationale. A process framework with tailoring guidelines is far more effective than a single, uniform process.
- Traceability: Most systems demand end-to-end traceability between requirements, design, implementation, verification results, and other artifacts.
- Tool and data integration: Processes can connect with product lifecycle management / application lifecycle management / configuration management (PLM/ALM/CM) tools to enable automation, audit trails, and reporting.
- Governance and accountability: Clear process ownership, change control boards, and role definitions prevent fragmentation and ensure accountability.

Additional topics of high relevance include:

- Human Factors and Organizational Aspects
  - Competence Management: Processes are only as good as the people executing them. Skills matrices, role training, and certification of staff should be part of the process framework.
  - Culture & Change Management: Process adoption depends strongly on company culture. Introducing new methods requires structured change management.
  - Communication Interfaces: Most systems often involve multiple disciplines. Defined communication rules and cross-disciplinary forums are essential.
- Knowledge and Lessons Learned

- Organizational Learning: Processes should include structured mechanisms for capturing lessons learned, good practices, and failure analyses.
- Reuse & Reference Architectures: Reusable components, design patterns, and product and process reference architectures can dramatically reduce risk and cost, but only if processes explicitly encourage and govern reuse.

Good Practices

Implementing effective and efficient processes for most systems goes beyond compliance; practical approaches that teams can consistently follow are required. The following good practices provide some guidance, however, tailoring to different project types, technologies, and organizational contexts should be considered.

- Lightweight Process Frameworks: Identify and build around core processes (e.g., requirements, architecture, integration, verification, validation, configuration, risk management). Overly detailed process definitions are often ignored. Focus first on essential practices. Note that the optimal process "weight" depends on mission criticality and risk.
- Tailoring: Define decision criteria (e.g., size, safety level, novelty, mission criticality, certification needs) to select mandatory vs. optional activities and level of rigor. Ensure tailoring is documented; clear decision trees and real-world examples improve adoption and compliance.
- Risk-based Verification: Scale test rigor and independence according to risk and criticality.
- Supplier governance: Require suppliers to demonstrate compliance and maturity.
- Training & coaching: Adoption requires skilled practitioners and process champions.
- Measurement and feedback loops: Collect data on defects, requirements churn, and lead times to refine processes.
- Management support: When process compliance is supported and demanded by management, lengthy debates about necessity are avoided. All levels of the project should be able to see the benefit of performing the processes.
- Pilot projects: Test process changes in representative projects before full rollout.
- Effectiveness vs efficiency: Processes must be effective before they can be made efficient. Getting the wrong answer faster or cheaper doesn't count.
- Process assurance: Life cycle processes form a basis for execution that avoids unintended omission, unnecessary activities and lack of discipline. For example, the project assessment and control process and decision management process provide for iterative incremental development that is at once responsive and disciplined.

Challenges

While a unified process framework offers consistency, in practice, no single process can perfectly fit every project or technology context. Differences in project size, complexity, regulatory requirements, and technology maturity can create conflicts that a single process cannot address. Typical challenges include:

- Scaling: Large programs can need more structure in their governance; small projects can leverage lean, flexible processes.
- Technology maturity: New technology requires experimentation; legacy products require strict control.
- Regulatory heterogeneity: Some domains demand exhaustive documentation, others allow leaner approaches.
- Organizational maturity: Processes that exceed a team's capability can lead to noncompliance.
- Culture Change, Change Management: Noncompliance also results from not having a common vision regarding the necessity, not getting adequate training, not providing for effective transition from previous process approaches, etc.
- Contractual constraints: OEMs, regulators, or funding bodies may impose specific processes.
- Myths about processes: ISO/IEC/IEEE 15288 "does not prescribe a specific system life cycle model, development methodology, method, modelling approach or technique" (ISO/IEC/IEEE 15288:2023, Clause 1). The processes, activities and tasks in ISO/IEC/IEEE 15288 can be used with agile and other techniques with or without tailoring.

Using ISO/IEC/IEEE 24748-2

- Lead Author:
- David Endler
- Contributing Author:
- Mike Yokell

-

Effective management of life cycle processes ensures quality, risk reduction, and consistency across projects. ISO/IEC/IEEE 15288 provides the foundational framework for system life cycle processes, often extended by domain-specific standards. ISO/IEC/IEEE 24748-2 guides the practical application of 15288 covering strategy, system, life cycle, organizational, project, process, and conformance aspects to ensure structured, adaptable implementation.

Fundamental Concepts

Management and structuring of life cycle processes are critical to achieving successful results. Life cycle processes provide a structured framework for all life cycle stages of systems or products. For organizations striving to ensure quality, reduce risk, and enhance consistency across projects, adopting recognized standards is not only recommended but often essential.

ISO/IEC/IEEE 15288 can be seen as the foundation for domain-specific standards (e.g., ASPICE, ISO 26262, RTCA DO-178C, RTCA DO-254, IEC 62304, ISO 13485), or as a framework for other standards and guides with specific focuses (e.g., ISO/IEC 27000, NIST 800-160, SAE 1001). In many situations it is therefore advisable to use this standard as a starting point and then overlay domain-specific standards to meet regulatory or certification requirements.

According to ISO/IEC/IEEE 24748-2: ISO/IEC/IEEE 24748-2 is a guideline for the application of ISO/IEC/IEEE 15288. It addresses system, life cycle, organizational, project, and process, concept application, principally through reference to ISO/IEC/IEEE 24748-1 and ISO/IEC/IEEE 15288. It gives guidance on applying ISO/IEC/IEEE 15288 from the aspects of strategy, planning, application in organizations, and application on projects. Whereas

ISO/IEC/IEEE 15288 is kept short and concise, ISO/IEC/IEEE 24784-2 elaborates on the following aspects:

- Application strategy
- Application of system concepts
- Application of life cycle concepts
- Application of organizational concepts
- Application of project concepts
- Application of process concepts
- Application of conformance and adaptation concepts

Application Strategy

Guidelines are provided for defining the strategy to apply ISO/IEC/IEEE 15288 to

- a specific project,
- improving an organization's life cycle processes, or
- system life cycle processes usable within a larger process (e.g., an organization's acquisition process).

The strategy described in ISO/IEC/IEEE 24748-2 includes the following steps:

- plan the application,
- adapt ISO/IEC/IEEE 15288, if applicable,
- conduct pilot project(s),
- formalize the approach, and
- institutionalize the approach.

Application of System Concepts

Approaches are summarized on how to define the system-of-interest, the system structure, as well as interfacing, enabling, and interoperating systems.

Application of life cycle concepts

This clause of ISO/IEC/IEEE 24748-2 summarizes

the generic life cycle stages,

the decision gates that separate the stages, and

application approaches.

Application of organizational concepts

Guidelines are provided on which topics should be considered when ISO/IEC/IEEE 15288 is applied internally by an organization or ISO/IEC/IEEE 15288 is applied through an agreement by two or more organizations.

Application of project concepts

This clause of ISO/IEC/IEEE 24748-2 summarizes how ISO/IEC/IEEE 15288 can be used by a project. Each of the four process groups (Agreement Processes, Organizational Project-Enabling Processes, Technical Management Processes, and Technical Processes) can be used to establish a common understanding in a project.

Application of process concepts

Detailed guidelines are provided for the life cycle processes defined in ISO/IEC/IEEE 15288.

Application of conformance and adaptation concepts

Guidelines for conformance and adaptation of the life cycle processes defined in ISO/IEC/IEEE 15288 are provided.

Tailoring

- Lead Author:
- David Endler
- Contributing Author:
- Mike Yokell

-

Project-level tailoring adapts ISO/IEC/IEEE 15288 processes to specific contexts, balancing rigor, risk, and flexibility. It is dynamic, evidence-based, and aligned with project planning. Success depends on stakeholder collaboration, documentation, and continuous review. Good practices emphasize fact-based decisions, tool integration, and adaptability, while avoiding over-engineering, uniformity, and neglecting stakeholder engagement.

Fundamental Concepts

While organizations provide governance and overarching frameworks (see articles Adapting the Life Cycle Model and Adapting the Development Approach), tailoring can be needed on the project level. ISO/IEC/IEEE 15288, along with related elaboration standards (ISO/IEC/IEEE 24748 series), defines a comprehensive set of life cycle processes that can be applied to projects of any size and complexity. However, no project can adopt these processes “off the shelf.” They should be tailored to the specific project environment, stakeholders, and risks.

The Role of Tailoring

Tailoring at the project level involves adjusting life cycle processes to ensure that they meet the unique requirements of the project. These adjustments scale the rigor of processes to a level appropriate to project risk, complexity, and constraints. For example:

- A project with tight budgets and low tolerance for failure can benefit more rigorous verification and validation activities.
- A small project with low complexity and high trust among stakeholders may streamline certain formal reviews to save cost and time.

Tailoring is not a one-time activity, but a dynamic process. As risks and circumstances evolve, tailoring should be revisited throughout the life cycle. As shown in Figure 1, it balances the dangers of two extremes:

Too little rigor, which raises the risk of technical issues, schedule slips, or cost overruns.

Too much rigor, which introduces unnecessary process overhead, reduces flexibility, and inflates cost.

PLACE FIGURE HERE

Figure 1: Tailoring requires balance between risk and process. INCOSE SEH original figure created by Krueger adapted from Salter (2003). Used with permission.

Project Context Factors

According to PMI Scaling Factors, several factors shape how tailoring decisions are made:

1. Team size
2. Geographic distribution
3. Organizational distribution
4. Skill availability
5. Compliance
6. Domain complexity
7. Solution complexity

Other factors that can be considered are:

1. Stakeholder landscape
2. Budget and schedule
3. Risk tolerance
4. Criticality of the project (safety, mission, etc.)

In all cases, tailoring seeks to ensure that processes are fit for purpose, supporting the project's goals while managing risk at an acceptable level.

Concurrency, Iteration, and Recursion

As described in article Process Concurrency, Iteration, and Recursion, life cycle processes are applied in ways that are concurrent, iterative, and recursive. For instance, requirements definition, architecture definition, and verification may occur simultaneously and in multiple cycles as knowledge evolves. The processes are recursively applied throughout the system structure. This recursive application ensures coherence across project activities and maintains traceability of decisions.

Good Practices

Project success depends on disciplined tailoring, transparent agreements, and effective use of tools and methods. Several practices have proven especially valuable.

Fact-Based Tailoring

Tailoring decisions should not rely on intuition alone. Instead, they should be based on facts, evidence, and risk assessment. Independent review or approval can help avoid bias. Using structured Decision Management processes to document alternatives, trade-offs, and rationales creates a traceable record that supports accountability.

Documenting and Validating Assumptions and Rationale

Every tailoring choice should be explicitly justified and recorded. For example, if a project reduces the number of formal design reviews, it should document why (e.g., high team cohesion, proven system element maturity). This documentation ensures that later stakeholders (especially during audits or project transitions) understand the reasoning behind earlier decisions.

Collaboration with Stakeholders

Projects rarely operate in isolation. Tailoring works best when all relevant stakeholders (e.g., acquirers, suppliers, and regulators) are involved in defining and approving the tailoring approach. Collaborative agreements build trust and reduce disputes later in the life cycle. As trust grows or project risks or complexity reduces[GR10] , projects can simplify some process activities; conversely, when risks rise, additional rigor can be introduced.

Integration with Project Planning

Tailoring should be conducted in parallel with project planning. Decisions on scope, schedule, budget, milestones, and resource allocation are tightly linked to the processes chosen or how they are applied. For example, aggressive schedules can require automated testing tools to accelerate verification, while budget constraints may limit the number of prototypes built. Alignment ensures that plans are realistic and processes are executable.

Dynamic Assessment and Control

Tailoring is not static. Throughout the project, effectiveness and efficiency of tailoring should be continuously assessed and, if necessary, controlled (see article Project Assessment and Control) in response to changing risks, stakeholder feedback, or external conditions. For example, if a project experiences unanticipated technical problems, additional design reviews can be added. Conversely, if risks decrease, some formalities can be reduced to save time.

Methods and Tools at Project Level

Though ISO/IEC/IEEE 15288 does not prescribe specific tools, projects benefit from structured selection and disciplined use of methods and tools. Key considerations include:

- Purpose-driven selection: Tools should directly support tailored processes; process comes before tool.
- Connectivity: Tools should integrate with other tools in use, ensuring smooth data flow across project functions.
- Training requirements: Staff need adequate preparation to use tools effectively.
- Engineer judgment: Tools are aids, not substitutes for critical thinking.
- Data availability: Tool selection should consider what data is needed and whether that data can easily be obtained and verified.

Practical Applications of Life Cycle Processes

According to ISO/IEC/IEEE 24748-2, ISO/IEC/IEEE 15288 processes can be applied in at least four practical ways:

- to establish agreements with organizational entities external and internal to the project to acquire or supply a product or service (agreement processes);
- to establish the organization's capability to acquire and supply products or services through the initiation, support and control of projects (organizational project-enabling processes);
- to establish and evolve project plans, to execute the project plans, to assess actual achievement and progress against the plans and to control execution of the project through to fulfilment (technical management processes);
- to contribute to the satisfaction of technical objectives for one or more life cycle stages (technical processes).

By focusing on these purposes, projects ensure that process tailoring delivers tangible value rather than administrative burden.

Challenges

Even with clear principles and good practices, projects face substantial challenges when tailoring and applying life cycle processes.

Common Tailoring Traps

Projects often fall into predictable traps, including:

- Reusing baselines blindly: Borrowing a tailored process from another project without revisiting assumptions.
- Over-engineering: Applying all processes "just to be safe," leading to unnecessary costs and delays.
- Assuming uniformity: Believing that the same set of risks or controls applies across all projects.
- Failing to engage stakeholders: Excluding key voices, which leads to lack of buy-in and increased risk of conflict.

Disciplined decision-making and continuous review can facilitate avoiding these traps.

Complexity of Multi-Stakeholder Projects

Projects often involve multiple stakeholders with different priorities and policies. Achieving alignment requires:

- Establishing consistent processes across parties.
- Negotiating agreements that balance competing needs.
- Using ISO/IEC/IEEE 15288 as a shared reference framework.
- Still, differences in culture, terminology, and expectations remain significant hurdles.

Tool and Method Pitfalls

On many cases, tools pose challenges:

- Lack of integration between tools creates silos and rework.
- Security and data management issues complicate tool lifecycle.
- High training requirements can strain limited project resources.
- Over-reliance on tools risks diminishing engineers' independent judgment.

Data availability and verification

- "Garbage in, Garbage out".

Maintaining Stakeholder Commitment

Tailoring of processes benefits from strong stakeholder commitment. If stakeholders view processes as excessive overhead, they can resist compliance. Conversely, if they perceive insufficient rigor, they may lose confidence in the project's ability to deliver. Active communication and visible leadership support are essential to maintain alignment.

Conclusion

At the project level, tailoring systems engineering life cycle processes is both a necessity and an opportunity. Standards such as ISO/IEC/IEEE 15288 provide a comprehensive framework, but projects should adapt these processes to their specific context, risks, and stakeholder environment.

Good practices include fact-based tailoring, documentation of rationale, stakeholder collaboration, integration with project planning, dynamic monitoring, and thoughtful tool use. By applying processes in ways that are practical and purpose-driven, projects can increase efficiency, reduce risk, and maintain stakeholder confidence.

Nevertheless, challenges remain. Projects should avoid common tailoring traps, balance rigor with agility, manage multi-stakeholder complexity, and ensure that tools support rather than dominate decision-making. Above all, continuous adaptation and transparent communication can help ensure that processes remain aligned with project needs.

In the end, project-level tailoring is not about minimizing process effort or maximizing bureaucracy. It is about applying the right processes, at the right level of rigor, at the right time to deliver systems that meet stakeholder needs effectively and efficiently.

This knowledge area is about managing the resources and assets allocated to perform systems engineering, often in the context of a project or a service, but sometimes in the context of a less well-defined activity. Systems engineering management is distinguished from general project management by its focus on the technical or engineering aspects of a project. SEM also encompasses exploratory research and development (R&D) activities at the enterprise level in commercial or government operations.

See the article Matrix of Implementation Examples for a mapping of case studies and vignettes included in Part 7 to topics covered in Part 3.

Discussion

Implementing systems engineering (SE) requires the coordination of technical and managerial endeavors. Success with the technical is not possible in the absence of the managerial. Management provides the planning, organizational structure, collaborative environment, and program controls to ensure that stakeholder needs are met.

The Venn diagram below provides some context for thinking about SEM. It shows that some functions are managed within the SE function, while others are managed in collaboration with the management of systems implementation and with overall project and systems management.

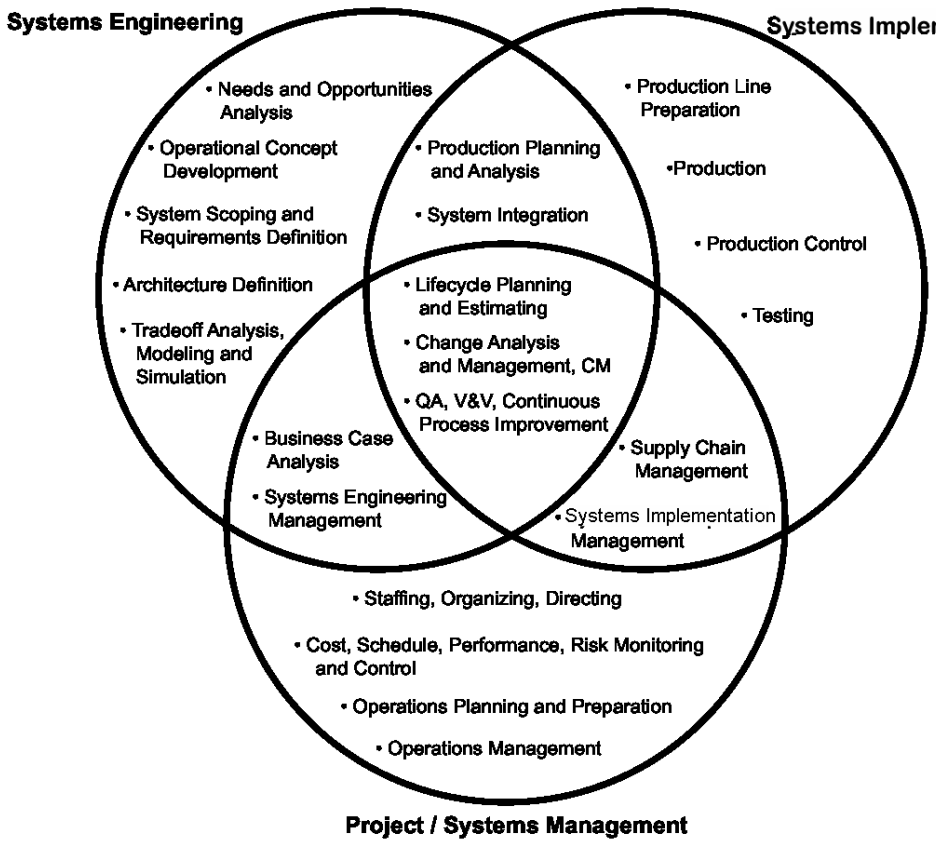

Figure 1. Systems Engineering Management Boundaries. (SEBoK Original)

There is no one-size-fits-all way to define the details of where SEM functions are performed. An in-company SE organization does not run its own accounting system, but relies on the corporate management organization for this aspect of SEM. A company performing only SE *does* include the accounting functions as part of SEM. In all cases, the managers of the SE function must be actively involved in the management of all the activities within the SE system boundary, including working out what collaborative arrangements best fit their situation. They must also remain aware of management events in their environment outside the system boundary that may affect their ability to perform. Part 6 of the SEBoK includes relevant knowledge areas for collaborative management, including Systems Engineering and Software Engineering, Systems Engineering and Project Management, Systems Engineering and Industrial Engineering, Systems Engineering and Procurement/Acquisition, and Systems Engineering and Quality Attributes.

Project Planning

- Lead Authors:
- Ray Madachy, Garry Roedler, and Brian Wells

-

Planning is an important aspect of technical management processes (SEM). Systems engineering (SE) planning is performed concurrently and collaboratively with project planning. It involves developing and integrating technical plans to achieve the technical project objectives within the resource constraints and risk thresholds. The planning involves the success-critical stakeholders to ensure that necessary tasks are defined with the right timing in the life cycle in order to manage acceptable risks levels, meet schedules, and avoid costly omissions.

SE Planning Process Overview

SE planning provides the following elements:

- Definition of the project from a technical perspective.
- Definition or tailoring of engineering processes, practices, methods, and supporting enabling environments to be used to develop products or services, as well as plans for transition and implementation of the products or services, as required by agreements.
- Definition of the technical organizational, personnel, and team functions and responsibilities, as well as all disciplines required during the project life cycle.
- Definition of the appropriate life cycle model or approach for the products or services.
- Definition and timing of technical reviews, product or service assessments, and control mechanisms across the life cycle, including the success criteria such as cost, schedule, and technical performance at identified project milestones.
- Estimation of technical cost and schedule based on the effort needed to meet the requirements; this estimation becomes input to project cost and schedule planning.
- Determination of critical technologies, as well as the associated risks and actions needed to manage and transition these technologies.
- Identification of linkages to other project management efforts.
- Documentation of and commitment to the technical planning.

Scope

SE planning begins with analyzing the scope of technical work to be performed and gaining an understanding the constraints, risks, and objectives that define and bound the solution space for the product or service. The planning includes estimating the size of the work products, establishing a schedule (or integrating the technical tasks into the project schedule), identification of risks, and negotiating commitments. Iteration of these planning tasks may be necessary to establish a balanced plan with respect to cost, schedule, technical performance, and quality. The planning continues to evolve with each successive life cycle phase of the project (NASA 2007, 1-360; SEI 1995, 12).

SE planning addresses all programmatic and technical elements of the project to ensure a comprehensive and integrated plan for all of the project's technical aspects and should account for the full scope of technical activities, including system development and definition, risk management, quality management, configuration management, measurement, information management, production, verification and testing, integration, validation, and deployment. SE planning integrates all SE functions to ensure that plans, requirements, operational concepts, and architectures are consistent and feasible.

The scope of planning can vary from planning a specific task to developing a major technical plan. The integrated planning effort will determine what level of planning and accompanying documentation is appropriate for the project.

Integration

The integration of each plan with other higher-level, peer, or subordinate plans is an essential part of SE planning. For the technical effort, the systems engineering management plan (SEMP), also frequently referred to as the systems engineering plan (SEP), is the highest-level technical plan. It is subordinate to the project plan and often has a number of subordinate technical plans providing detail on specific technical focus areas (INCOSE 2011, sec. 5.1.2.2; NASA 2007, appendix J).

In U.S. defense work, the terms SEP and SEMP are not interchangeable. The SEP is a high-level plan that is made before the system acquisition and development begins. It is written by the government customer. The SEMP is the specific development plan written by the developer (or contractor). In this context, intent, and content of these documents are quite different. For example, a SEP will have an acquisition plan that would not be included in a SEMP. Figure 1 below shows the SEMP and integrated plans.

Figure 1. SEMP and Integrated Plans. (SEBoK Original)

Task planning identifies the specific work products, deliverables, and success criteria for systems engineering efforts in support of integrated planning and project objectives. The success criteria are defined in terms of cost, schedule, and technical performance at identified project milestones. Detailed task planning identifies specific resource requirements (e.g., skills, equipment, facilities, and funding) as a function of time and project milestones.

SE planning is accomplished by both the acquirer and supplier and the activities for SE planning are performed in the context of the respective enterprise. The activities establish and identify relevant policies and procedures for managing and executing the project management and technical effort, identifying the management and technical tasks, their interdependencies, risks, and opportunities, and providing estimates of needed resources/budgets. Plans are updated and refined throughout the development process based on status updates and evolving project requirements (SEI 2007).

Linkages to Other Systems Engineering Management Topics

The project planning process is closely coupled with the measurement, assessment and control, decision management, and risk management processes.

The measurement process provides inputs for estimation models. Estimates and other products from planning are used in decision management. SE assessment and control processes use planning results for setting milestones and assessing progress. Risk management uses the planning cost models, schedule estimates, and uncertainty distributions to support quantitative risk analysis (as desired).

Additionally, planning needs to use the outputs from assessment and control as well as risk management to ensure corrective actions have been accounted for in planning future activities. The planning may need to be updated based on results from technical reviews (from assessment and control) addressing issues pertaining to: measurement, problems that were identified during the performance of risk management activities, or decisions made as a result of

the decision management activities (INCOSE 2010, sec. 6.1).

Practical Considerations

Pitfalls

Some of the key pitfalls encountered in planning and performing SE planning are listed in Table 1.

Table 1. Major Pitfalls with Planning. (SEBoK Original)

Name	Description
Incomplete and Rushed Planning	Inadequate SE planning causes significant adverse impacts on all other engineering activities. Although one may be tempted to save time by rushing the planning, inadequate planning can create additional costs and interfere with the schedule due to planning omissions, lack of detail, lack of integration of efforts, infeasible cost and schedules, etc.
Inexperienced Staff	Lack of highly experienced engineering staff members, especially in similar projects, will likely result in inadequate planning. Less experienced engineers are often assigned significant roles in the SE planning; however, they may not have the appropriate judgment to lay out realistic and achievable plans. It is essential to assign the SE planning tasks to those with a good amount of relevant experience.

Good Practices

Some good practices gathered from the references are in Table 2.

Table 2. Proven Practices with Planning. (SEBoK Original)

Name	Description
Use Multiple Disciplines	Get technical resources from all disciplines involved in the planning process.
Early Conflict Resolution	Resolve schedule and resource conflicts early.
Task Independence	Tasks should be as independent as possible.
Define Interdependencies	Define task interdependencies, using dependency networks or other approaches.
Risk Management	Integrate risk management with the SE planning to identify areas that require special attention and/or trades.
Management Reserve	The amount of management reserve should be based on the risk associated with the plan.
Use Historical Data	Use historical data for estimates and adjust for differences in the project.
Consider Lead Times	Identify lead times and ensure that you account for them in the planning (e.g., the development of analytical tools).
Update Plans	Prepare to update plans as additional information becomes available or changes are needed.
Use IPDTs	An integrated product development team (IPDT) (or integrated product team (IPT)) is often useful to ensure adequate communication across the necessary disciplines, timely integration of all design considerations, as well as integration, testing, and consideration of the full range of risks that need to be addressed. Although there are some issues that need to be managed with them, IPDTs tend to break down the communication and knowledge stovepipes that often exist.

Additional good practices can be found in the *Systems Engineering Guidebook for Intelligent Transportation Systems (ITS)*, *NASA Systems Engineering Handbook*, the *INCOSE Systems Engineering Handbook*, and *Systems and Software Engineering - Life Cycle Processes - Project Management* (Caltrans and USDOT 2005, 278; NASA December 2007, 1-360, sec. 6.1; INCOSE 2011, sec. 5.1; ISO/IEC/IEEE 2009, Clause 6.1).

Project Assessment and Control

- Lead Authors:
- Ray Madachy, Andy Pickard, and Garry Roedler
- Contributing Author:
- Richard Turner

-

The purpose of systems engineering assessment and control (SEAC) is to provide adequate visibility into the project's actual technical progress and risks with respect to the technical plans (i.e., systems engineering management plan (SEMP) or systems engineering plan (SEP) and subordinate plans). The visibility allows the project team to take timely preventive action when disruptive trends are recognized or corrective action when performance deviates beyond established thresholds or expected values. SEAC includes preparing for and conducting reviews and audits to monitor performance. The results of the reviews and measurement analyses are used to identify and record findings/discrepancies and may lead to causal analysis and corrective/preventive action plans. Action plans are implemented, tracked, and monitored to closure. (NASA 2007, Section 6.7; SEG-ITS, 2009, Section 3.9.3, 3.9.10; INCOSE, 2010, Clause 6.2; SEI, 2007)

Systems Engineering Assessment and Control Process Overview

The SEAC process involves determining and initiating the appropriate handling strategies and actions for findings and/or discrepancies that are uncovered in the enterprise, infrastructure, or life cycle activities associated with the project. Analysis of the causes of the findings/discrepancies aids in the determination of appropriate handling strategies. Implementation of approved preventive, corrective, or improvement actions ensures satisfactory completion of the project within planned technical, schedule, and cost objectives. Potential action plans for findings and/or discrepancies are reviewed in the context of the overall set of actions and priorities in order to optimize the benefits to the project and/or organization. Interrelated items are analyzed together to obtain a consistent and cost-effective resolution.

The SEAC process includes the following steps:

- monitor and review technical performance and resource use against plans
- monitor technical risk, escalate significant risks to the project risk register and seek project funding to execute risk mitigation plans
- hold technical reviews and report outcomes at the project reviews
- analyze issues and determine appropriate actions
- manage actions to closure

- hold a post-delivery assessment (also known as a post-project review) to capture knowledge associated with the project (this may be a separate technical assessment or it may be conducted as part of the project assessment and control process).

The following activities are normally conducted as part of a project assessment and control process:

- authorization, release and closure of work
- monitor project performance and resource usage against plan
- monitor project risk and authorize expenditure of project funds to execute risk mitigation plans
- hold project reviews
- analyze issues and determine appropriate actions
- manage actions to closure
- hold a post-delivery assessment (also known as a post-project review) to capture knowledge associated with the project

Examples of major technical reviews used in SEAC are shown in Table 1 from DAU (2010).

Table 1. Major Technical Review Examples (DAU 2012). Released by Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

Name	Description
Alternative Systems Review	A multi-disciplined review to ensure the resulting set of requirements agrees with the customers' needs and expectations.
Critical Design Review (CDR)	A multi-disciplined review establishing the initial product baseline to ensure that the system under review has a reasonable expectation of satisfying the requirements of the capability development document within the currently allocated budget and schedule.
Functional Configuration Audit	Formal examination of the as-tested characteristics of a configuration item (hardware and software) with the objective of verifying that actual performance complies with design and interface requirements in the functional baseline.
In-Service Review	A multi-disciplined product and process assessment that is performed to ensure that the system under review is operationally employed with well-understood and managed risk.
Initial Technical Review	A multi-disciplined review that supports a program's initial program objective memorandum submission.
Integrated Baseline Review	A joint assessment conducted by the government program manager and the contractor to establish the performance measurement baseline.
Operational Test Readiness Review	A multi-disciplined product and process assessment to ensure that the system can proceed into initial operational test and evaluation with a high probability of success, and also that the system is effective and suitable for service introduction.
Production Readiness Review (PRR)	The examination of a program to determine if the design is ready for production and if the prime contractor and major subcontractors have accomplished adequate production planning without incurring unacceptable risks that will breach thresholds of schedule, performance, cost, or other established criteria.
Physical Configuration Audit	An examination of the actual configuration of an item being produced around the time of the full-rate production decision.
Preliminary Design Review (PDR)	A technical assessment establishing the physically allocated baseline to ensure that the system under review has a reasonable expectation of being judged operationally effective and suitable.
System Functional Review (SFR)	A multi-disciplined review to ensure that the system's functional baseline is established and has a reasonable expectation of satisfying the requirements of the initial capabilities document or draft capability development document within the currently allocated budget and schedule.
System Requirements Review (SRR)	A multi-disciplined review to ensure that the system under review can proceed into initial systems development and that all system requirements and performance requirements derived from the initial capabilities document or draft capability development document are defined and testable, as well as being consistent with cost, schedule, risk, technology readiness, and other system constraints.

System Verification Review (SVR)	A multi-disciplined product and process assessment to ensure the system under review can proceed into low-rate initial production and full-rate production within cost (program budget), schedule (program schedule), risk, and other system constraints.
Technology Readiness Assessment	A systematic, metrics-based process that assesses the maturity of critical technology elements, such as sustainment drivers.
Test Readiness Review (TRR)	A multi-disciplined review designed to ensure that the subsystem or system under review is ready to proceed into formal testing.

Linkages to Other Systems Engineering Management Topics

The SE assessment and control process is closely coupled with the measurement, planning, decision management, and risk management processes. The measurement process provides indicators for comparing actuals to plans. Planning provides estimates and milestones that constitute plans for monitoring as well as the project plan, which uses measurements to monitor progress. Decision management uses the results of project monitoring as decision criteria for making control decisions.

Practical Considerations

Key pitfalls and good practices related to SEAC are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing SE assessment and control are shown in Table 2.

Table 2. Major Pitfalls with Assessment and Control. (SEBoK Original)

Name	Description
No Measurement	Since the assessment and control activities are highly dependent on insightful measurement information, it is usually ineffective to proceed independently from the measurement efforts - what you get is what you measure.
"Something in Time" Culture	Some things are easier to measure than others - for instance, delivery to cost and schedule. Don't focus on these and neglect harder things to measure like quality of the system. Avoid a "something in time" culture where meeting the schedule takes priority over everything else, but what is delivered is not fit for purpose, resulting in the need to rework the project.
No Teeth	Make sure that the technical review gates have "teeth". Sometimes the project manager is given authority (or can appeal to someone with authority) to over-ride a gate decision and allow work to proceed, even when the gate has exposed significant issues with the technical quality of the system or associated work products. This is a major risk if the organization is strongly schedule-driven; it can't afford the time to do it right, but somehow it finds the time to do it again (rework).
Too Early Baselining	Don't baseline requirements or designs too early. Often there is strong pressure to baseline system requirements and designs before they are fully understood or agreed, in order to start subsystem or component development. This just guarantees high levels of rework.

Good Practices

Some good practices gathered from the references are shown in Table 3.

Table 3. Proven Practices with Assessment and Control. (SEBoK Original)

Name	Description
Independence	Provide independent (from customer) assessment and recommendations on resources, schedule, technical status, and risk based on experience and trend analysis.
Peer Reviews	Use peer reviews to ensure the quality of a product's work before they are submitted for gate review.
Accept Uncertainty	Communicate uncertainties in requirements or designs and accept that uncertainty is a normal part of developing a system.
Risk Mitigation Plans	Do not penalize a project at gate review if they admit uncertainty in requirements - ask for their risk mitigation plan to manage the uncertainty.
Just In-Time Baselining	Baseline requirements and designs only when you need to - when other work is committed based on the stability of the requirement or design. If work must start and the requirement or design is still uncertain, consider how you can build robustness into the system to handle the uncertainty with minimum rework.
Communication	Document and communicate status findings and recommendations to stakeholders.
Full Visibility	Ensure that action items and action-item status, as well as other key status items, are visible to all project participants.
Leverage Previous Root Cause Analysis	When performing root cause analysis, take into account the root cause and resolution data documented in previous related findings/discrepancies.
Concurrent Management	Plan and perform assessment and control concurrently with the activities for Measurement and Risk Management.
Lessons Learned and Post-Mortems	Hold post-delivery assessments or post-project reviews to capture knowledge associated with the project – e.g., to augment and improve estimation models, lessons learned databases, gate review checklists, etc.

Additional good practices can be found in INCOSE (2010, Clause 6.2), SEG-ITS (2009, Sections 3.9.3 and 3.9.10), INCOSE (2010, Section 5.2.1.5), and NASA (2007, Section 6.7).

Decision Management

- Lead Author:
- Matt Chilli
- Contributing Authors:
- Garry Roedler, Greg Parnell, and Scott Jackson

-

Many systems engineering decisions are difficult because they include numerous stakeholders, multiple competing objectives, substantial uncertainty, and significant consequences. In these cases, good decision making requires a formal decision management process. The purpose of the decision management process is:

> "…to provide a structured, analytical framework for objectively identifying, characterizing and evaluating a set of alternatives for a decision at any point in the life cycle and select the most beneficial course of action."(ISO/IEC/IEEE 15288)

Decision situations (opportunities) are commonly encountered throughout a system's lifecycle. The decision management method most commonly employed by systems engineers is the trade study. Trade studies aim to define, measure, and assess shareholder and stakeholder value to facilitate the decision maker's search for an alternative that represents the best balance of competing objectives. By providing techniques for decomposing a trade decision into logical segments and then synthesizing the parts into a coherent whole, a decision management process allows the decision maker to work within human cognitive limits without oversimplifying the problem. Furthermore, by decomposing the overall decision problem, experts can provide assessments of alternatives in their area of expertise.

Decision Management Process

The decision analysis process is depicted in Figure 1 below. The decision management process is based on several best practices, including:

- Utilizing sound mathematical technique of decision analysis for trade studies. Parnell (2009) provided a list of decision analysis concepts and techniques.
- Developing one master decision model, followed by its refinement, update, and use, as required for trade studies throughout the system life cycle.
- Using Value-Focused Thinking (Keeney 1992) to create better alternatives.
- Identifying uncertainty and assessing risks for each decision.

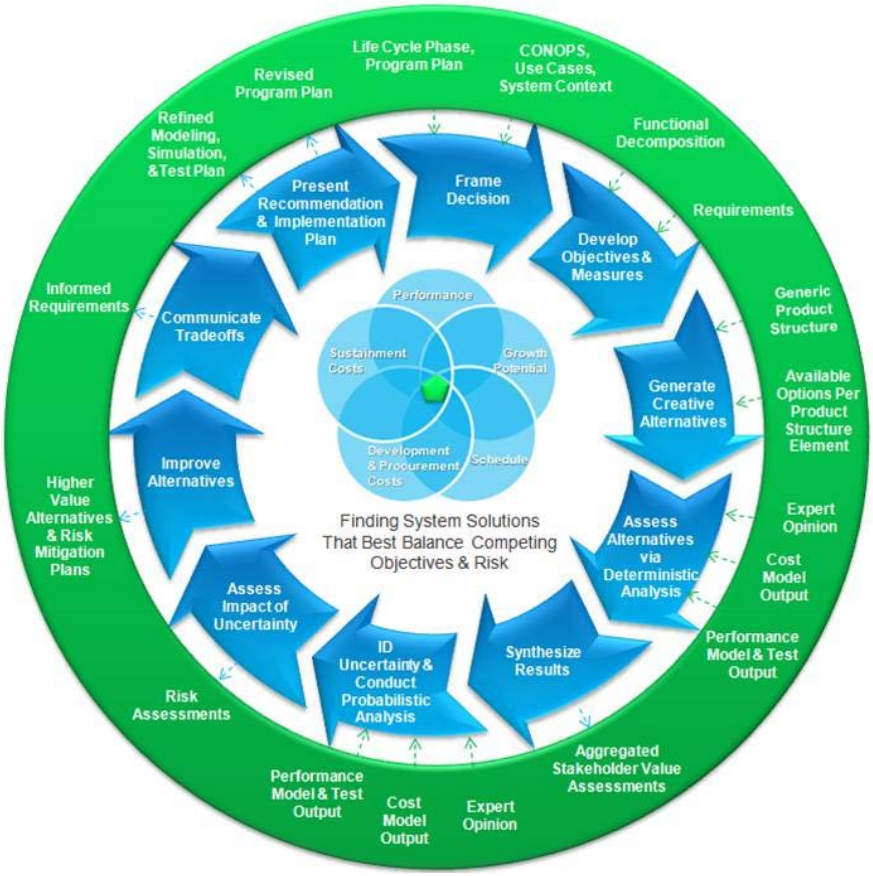

Figure 1. Decision Management Process (INCOSE DAWG 2013). Permission granted by Matthew Cilli who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

The center of the diagram shows the five trade space objectives (listed clockwise): Performance, Growth Potential, Schedule, Development & Procurement Costs, and Sustainment Costs . The ten blue arrows represent the decision management process activities and the white text within the green ring represents SE process elements. Interactions are represented by the small, dotted green or blue arrows. The decision analysis process is an iterative process. A hypothetical UAV decision problem is used to illustrate each of the activities in the following sections.

Framing and Tailoring the Decision

To ensure the decision team fully understands the decision context, the analyst should describe the system baseline, boundaries and interfaces. The decision context includes: the system definition, the life cycle stage, decision milestones, a list of decision makers and stakeholders, and available resources. The best practice is to identify a decision problem statement that defines the decision in terms of the system life cycle.

Developing Objectives and Measures

Defining how an important decision will be made is difficult. As Keeney (2002) puts it:

> *Most important decisions involve multiple objectives, and usually with multiple-objective decisions, you can't have it all. You will have to accept less achievement in terms of some objectives in order to achieve more on other objectives. But how much less would you accept to achieve how much more?*

The first step is to develop objectives and measures using interviews and focus groups with subject matter experts (SMEs) and stakeholders. For systems engineering trade-off analyses, stakeholder value often includes competing objectives of performance, development schedule, unit cost, support costs, and growth potential. For corporate decisions, shareholder value would also be added to this list. For performance, a functional decomposition can help generate a thorough set of potential objectives. Test this initial list of fundamental objectives by checking that each fundamental objective is essential and controllable and that the set of objectives is complete, non-redundant, concise, specific, and understandable (Edwards et al. 2007). Figure 2 provides an example of an objectives hierarchy.

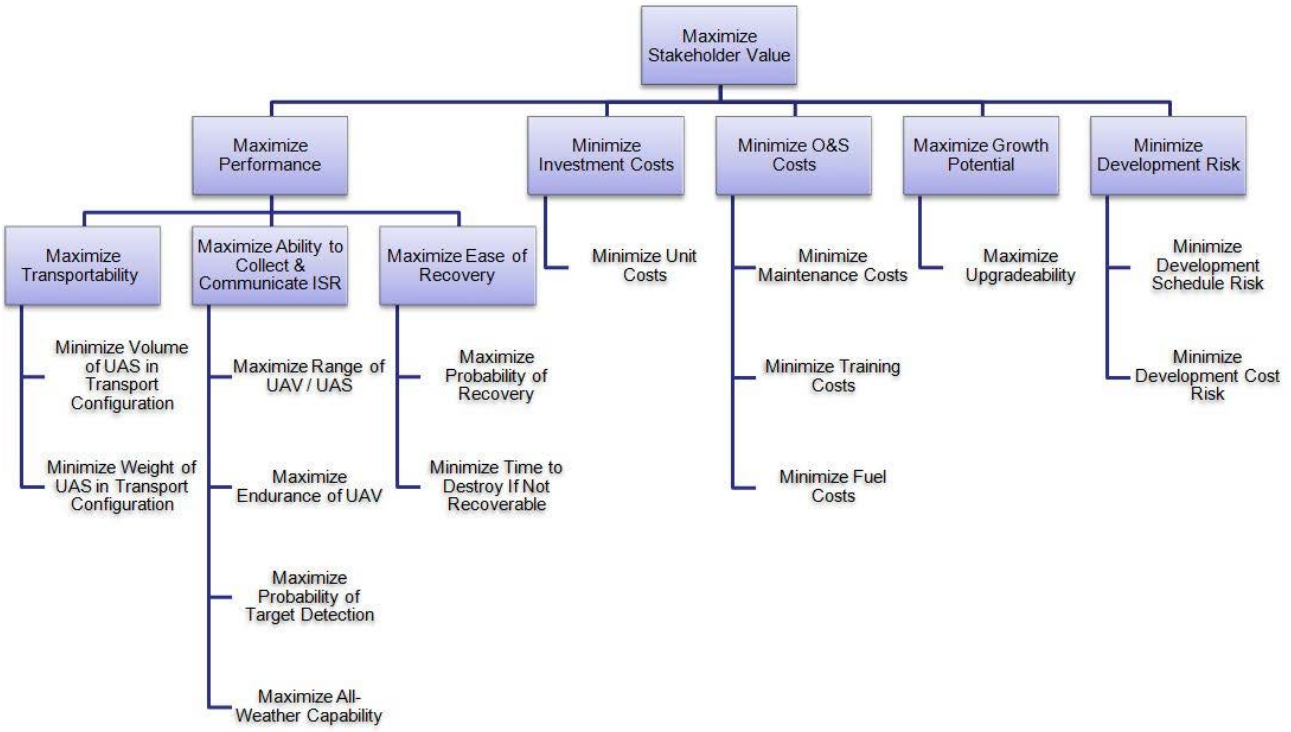

Figure 2. Fundamental Objectives Hierarchy (INCOSE DAWG 2013). Permission granted by Matthew Cilli who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

For each objective, a measure must be defined to assess the value of each alternative for that objective. A measure (attribute, criterion, and metric) must be unambiguous, comprehensive, direct, operational, and understandable (Keeney & Gregory 2005). A defining feature of multi-objective decision analysis is the transformation from measure space to value space. This transformation is performed by a value function which shows returns to scale on the measure range. When creating a value function, the walk-away point on the measure scale (x-axis) must be ascertained and mapped to a 0 value on the value scale (y-axis). A walk-away point is the measure score where

regardless of how well an alternative performs in other measures, the decision maker will walk away from the alternative. He or she does this through working with the user, finding the measure score beyond, at which point an alternative provides no additional value, and labeling it "stretch goal" (ideal) and then mapping it to 100 (or 1 and 10) on the value scale (y-axis). Figure 3 provides the most common value curve shapes. The rationale for the shape of the value functions should be documented for traceability and defensibility (Parnell et al. 2011).

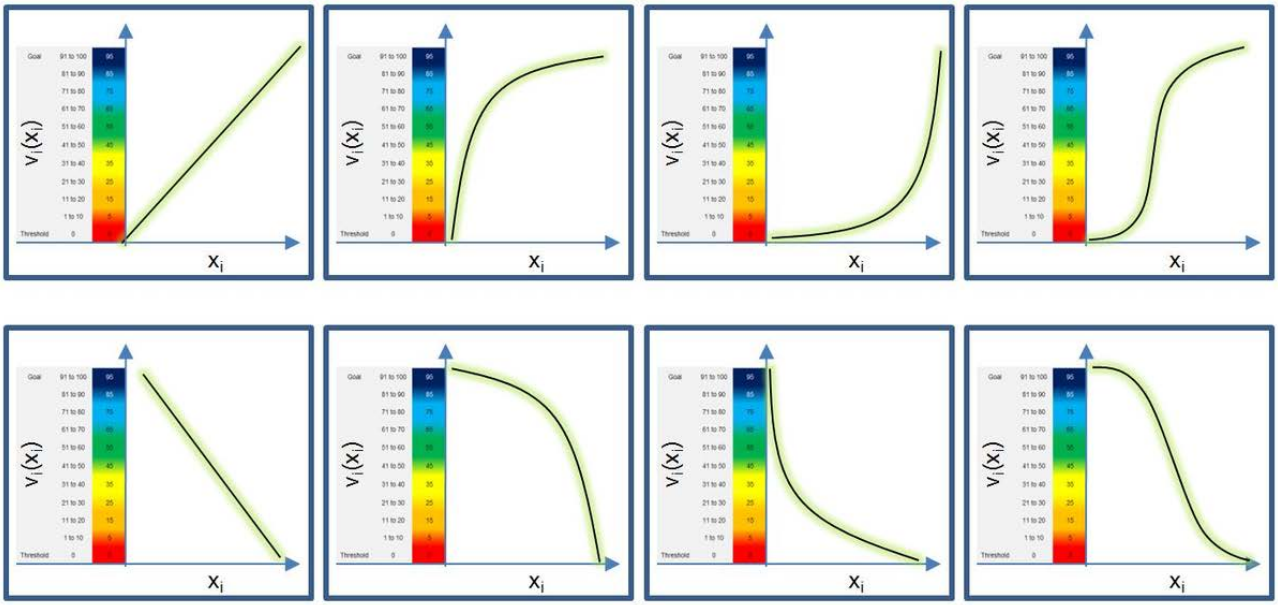

Figure 3. Value Function Examples (INCOSE DAWG 2013). Permission granted by Matthew Cilli who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

The mathematics of multiple objective decision analysis (MODA) requires that the weights depend on importance of the measure and the range of the measure (walk away to stretch goal). A useful tool for determining priority weighting is the swing weight matrix (Parnell et al. 2011). For each measure, consider its importance through determining whether the measure corresponds to a defining, critical, or enabling function and consider the gap between the current capability and the desired capability; finally, put the name of the measure in the appropriate cell of the matrix (Figure 4). The highest priority weighting is placed in the upper-left corner and assigned an unnormalized weight of 100. The unnormalized weights are monotonically decreasing to the right and down the matrix. Swing weights are then assessed by comparing them to the most important value measure or another assessed measure. The swing weights are normalized to sum to one for the additive value model used to calculate value in a subsequent section.

Highest Weight		Level of importance of the value measure								
		Mission Critical	Swt	Mwt	Mission Effectiveness	Swt	Mwt	Mission Enhancing	Swt	Mwt
Capability gap	Large	UAV range in nm	100	0.285	All weather capability	50	0.142	UAV P[R]	10	0.028
	Medium	UAV endurance in minutes	80	0.228	UAS volume in ft3	40	0.114			
	Small	UAV P[D]	50	0.142	UAS weight in pounds	20	0.057	UAV destruct time in seconds	1	0.003
Total swing weight			351		f_i = swing weight			w_i = measure weight	$w_i = \frac{f_i}{\sum_{i=1}^{n} f_i}$	

Figure 4. Swing Weight Matrix (INCOSE DAWG 2013). Permission granted by Gregory Parnell who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

Generating Creative Alternatives

To help generate a creative and comprehensive set of alternatives that span the decision space, consider developing an alternative generation table (also called a morphological box) (Buede, 2009; Parnell et al. 2011). It is a best practice to establish a meaningful product structure for the system and to be reported in all decision presentations (Figure 5).

Assessing Alternatives via Deterministic Analysis

With objectives and measures established and alternatives having been defined, the decision team should engage SMEs, equipped with operational data, test data, simulations, models, and expert knowledge. Scores are best captured on scoring sheets for each alternative/measure combination which document the source and rationale. Figure 6 provides a summary of the scores.

Raw Scorecard (expected pefromance values)			RELOCATE UAV		EMPLOY UAV				RECOVER UAV		GROWTH POT.	UNIT COST	DEVELOPMENT RISK		OPERATION & SUPPORT COST		
			Minimize UAV weight	Minimize UAV volume	Maximize all weather capability	Maximize UAV range	Maximize UAV probability of detection	Maximize UAV endurance	Maximize probability of recovery	Minimize time to destroy if not recoverable	Maximize upgradability	Minimize unit cost	Minimize development schedule risk	Minimize development cost risk	Minimize training cost	Minimize maintenance cost	Minimize fuel cost
ID	Name	Image	(lbs)	ft3	index	km	P[D]	hours	P[R]	sec	index	FY13$K	index	index	FY13$	FY13$	FY13$

7	Ideal		5	10	5	100	1	2	0.9	1	1	200	1	1	250	0	0

Figure 6. Alternative Scores (INCOSE DAWG 2013). Permission granted by Richard Swanson who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

Note that in addition to identified alternatives, the score matrix includes a row for the ideal alternative. The ideal is a tool for value-focused thinking, which will be covered later.

Synthesizing Results

Next, one can transform the scores into a value table, by using the value functions developed previously. A color heat map can be useful to visualize value tradeoffs between alternatives and identify where alternatives need improvement (Figure 7).

		Heat-indexed Value Scorecard	RELOCATE UAV		EMPLOY UAV				RECOVER UAV		GROWTH POT.	UNIT COST	DEVELOPMENT RISK		OPERATION & SUPPORT COST		
			Minimize UAV weight	Minimize UAV volume	Maximize all weather capability	Maximize UAV range	Maximize UAV probability of detection	Maximize UAV endurance	Maximize probability of recovery	Minimize time to destroy if not recoverable	Maximize upgradability	Minimize unit cost	Minimize development schedule risk	Minimize development cost risk	Minimize training cost	Minimize maintenance cost	Minimize fuel cost

Figure 7. Value Scorecard with Heat Map (INCOSE DAWG 2013). Permission granted by Richard Swanson who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

The additive value model uses the following equation to calculate each alternative's value:

$$v(x) = \sum_{i=1}^{n} w_i v_i(x_i)$$

where

$v(x)$ is the alternative's value

$i = 1 \; to \; n$ is the number of the measure

x_i is the alternative's score on the i^{th} measure

$v_i(x_i)$ is the single dimensional value of a score of x_i

w_i is the weight of the i^{th} measure

and $\sum_{i=1}^{n} w_i = 1$ (all weights sum to one)

The value component chart (Figure 8) shows the total value and the weighted value measure contribution of each alternative (Parnell et al. 2011).

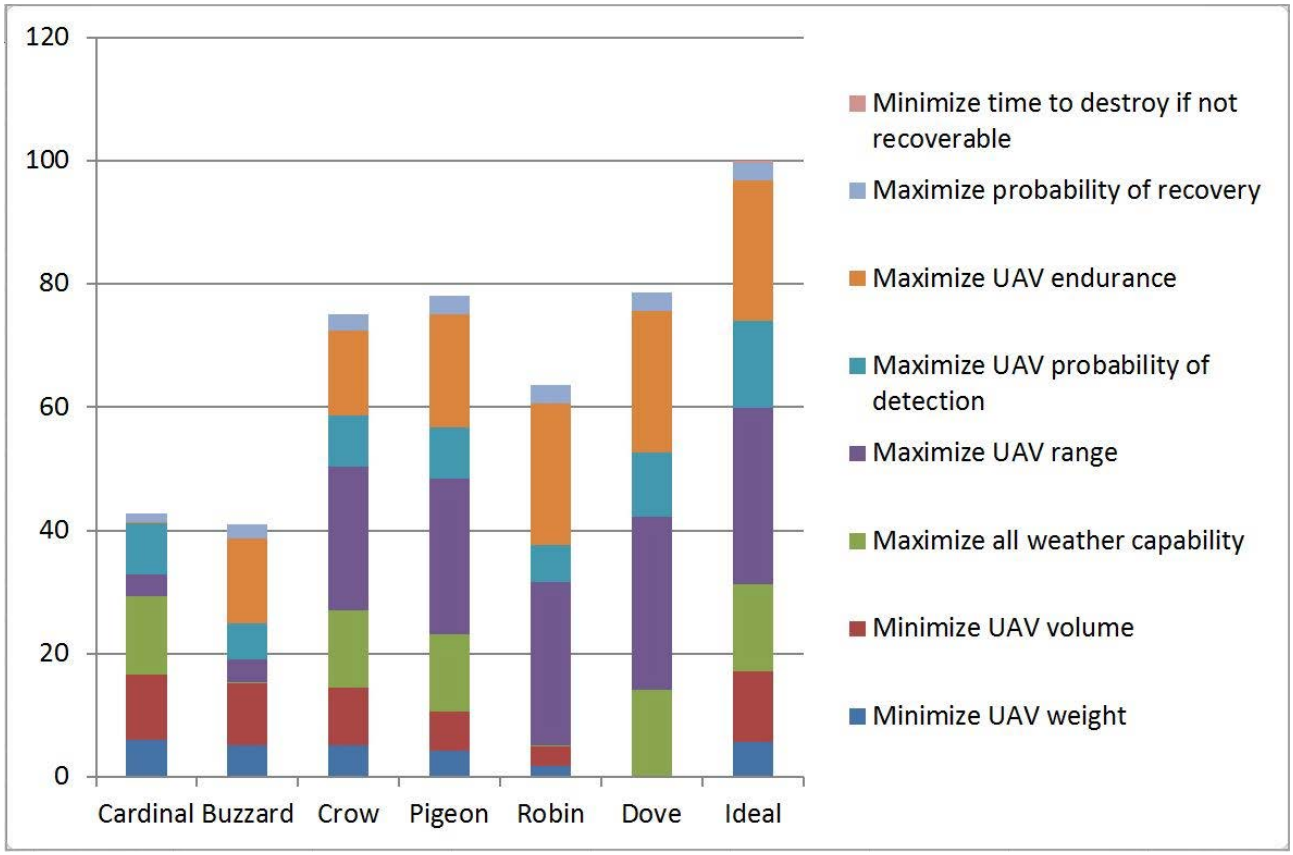

Figure 8. Value Component Graph (INCOSE DAWG 2013). Permission granted by Richard Swanson who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

The heart of a decision management process for system engineering trade off analysis is the ability to assess all dimensions of shareholder and stakeholder value. The stakeholder value scatter plot in Figure 9 shows five dimensions: unit cost, performance, development risk, growth potential, and operation and support costs for all alternatives.

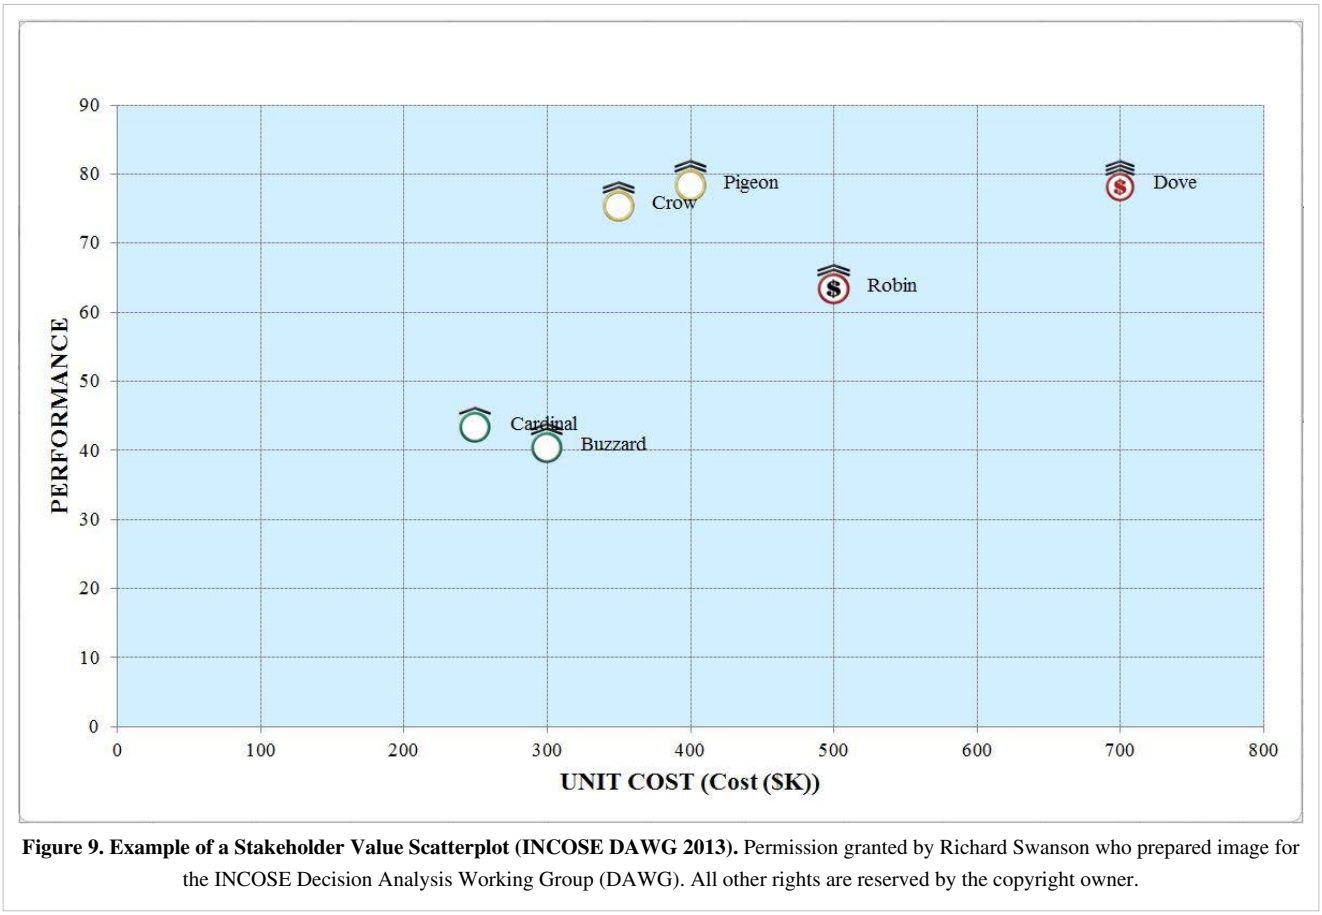

Figure 9. Example of a Stakeholder Value Scatterplot (INCOSE DAWG 2013). Permission granted by Richard Swanson who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

Each system alternative is represented by a scatter plot marker (Figure 9). An alternative's unit cost and performance value are indicated by x and y positions respectively. An alternative's development risk is indicated by the color of the marker (green = low, yellow= medium, red = high), while the growth potential is shown as the number of hats above the circular marker (1 hat = low, 2 hats = moderate, 3 hats = high).

Identifying Uncertainty and Conducting Probabilistic Analysis

As part of the assessment, the SME should discuss the potential uncertainty of the independent variables. The independent variables are the variables that impact one or more scores; the scores that are independent scores. Many times the SME can assess an upper, nominal, and lower bound by assuming low, moderate, and high performance. Using this data, a Monte Carlo Simulation summarizes the impact of the uncertainties and can identify the uncertainties that have the most impact on the decision.

Accessing Impact of Uncertainty - Analyzing Risk and Sensitivity

Decision analysis uses many forms of sensitivity analysis including line diagrams, tornado diagrams, waterfall diagrams and several uncertainty analyses including Monte Carlo Simulation, decision trees, and influence diagrams (Parnell et al. 2013). A line diagram is used to show the sensitivity to the swing weight judgment (Parnell et al. 2011). Figure 10 shows the results of a Monte Carlo Simulation of performance value.

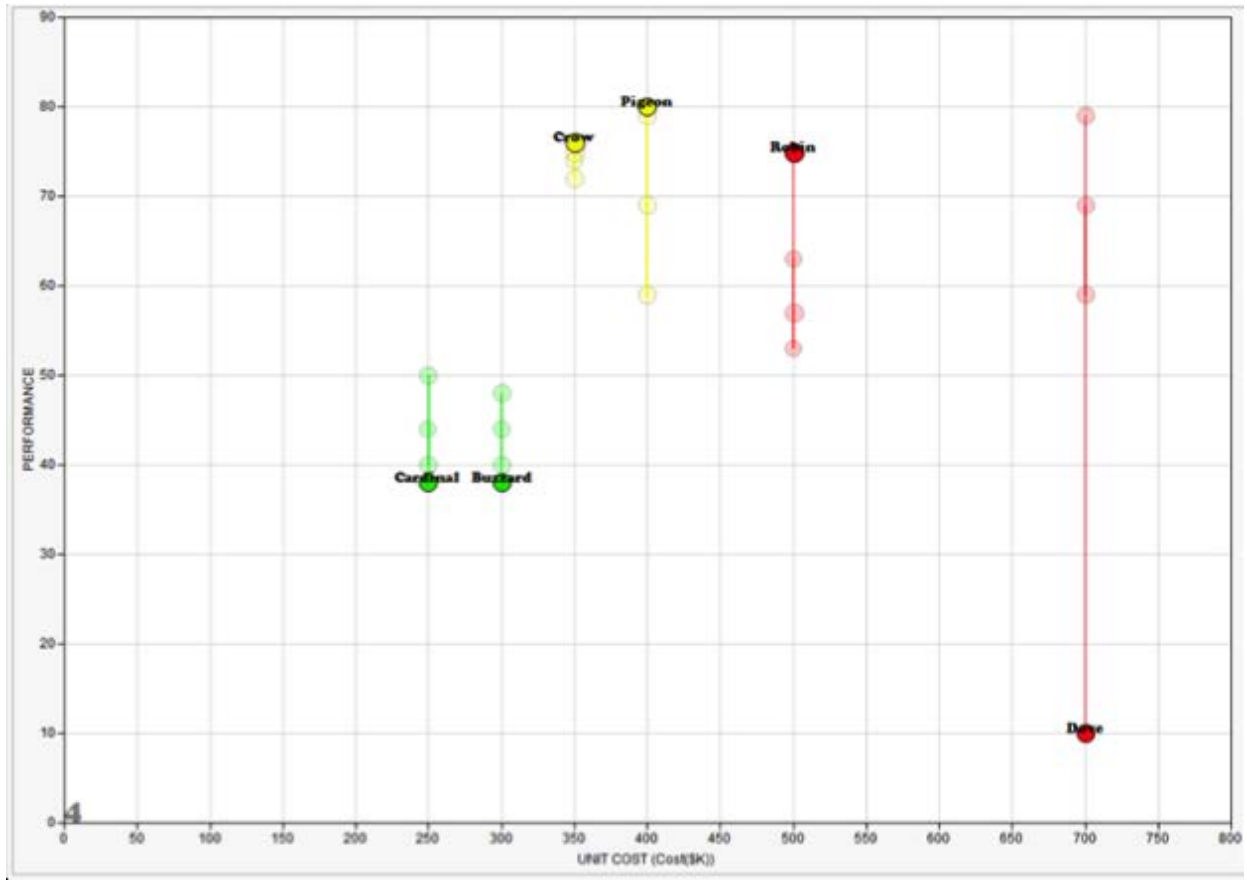

Figure 10. Uncertainty on Performance Value from Monte Carlo Simulation (INCOSE DAWG 2013). Permission granted by Matthew Cilli who prepared image for the INCOSE Decision Analysis Working Group (DAWG). All other rights are reserved by the copyright owner.

Improving Alternatives

Mining the data generated for the alternatives will likely reveal opportunities to modify some design choices to claim untapped value and/or reduce risk. Taking advantage of initial findings to generate new and creative alternatives starts the process of transforming the decision process from "alternative-focused thinking" to "value-focused thinking" (Keeney 1993).

Communicating Tradeoffs

This is the point in the process where the decision analysis team identifies key observations about tradeoffs and the important uncertainties and risks.

Presenting Recommendations and Implementing Action Plan

It is often helpful to describe the recommendation(s) in the form of a clearly-worded, actionable task-list in order to increase the likelihood of the decision implementation. Reports are important for historical traceability and future decisions. Take the time and effort to create a comprehensive, high-quality report detailing study findings and supporting rationale. Consider static paper reports augmented with dynamic hyper-linked e-reports.

The Cognitive Bias Effect on Decisions

Research by (Kahneman 2011) and (Thaler and Sunstein 2008) has concluded that cognitive bias can seriously distort decisions made by any decision maker. Both Kahneman and Thaler were awarded the Nobel prize for their work. The cause of this distortion is called the cognitive bias. These distorted decisions have contributed to major catastrophes, such as Challenger and Columbia. Other sources attributing major catastrophes are (Murata, Nakamura, and Karwowski 2015) and (Murata 2017).

(Kahneman 2011) and (Thaler and Sunstein 2008) have identified a large number of individual biases, the most well-known of which is the confirmation bias. This bias states that humans have a tendency to interpret new evidence as confirmation of one's existing beliefs or theories. Regarding mitigation of theses biases, there is general agreement that self-mitigation by the decision-maker is not feasible for most biases. (Thaler and Sunstein 2008) provide methods to influence the mitigation of most biases. They refer to these influences as “nudges”.

Considering cognitive biases in a systems engineering is discussed by (Jackson 2017, Jackson and Harel 2017), and (Jackson 2018). The primary theme of these references is that rational decisions are rarely possible and that cognitive bias must be taken into account.

Decisions with Cognitive Bias

According to (INCOSE 2015) ideal decisions are made while “objectively identifying, characterizing, and evaluating a set of alternatives for a decision…” Research in the field of behavioral economics has shown that these decisions can be distorted by a phenomenon known as cognitive bias. Furthermore, most decision makers are unaware of these biases. The literature also provides methods for mitigating these biases.

According to (Haselton, Nettle, and Andrews 2005, p. 2) a cognitive bias represents a situation in which “human cognition reliably produces representations that are systematically distorted compared to some aspect of objective reality.” Cognitive biases are typically stimulated by emotion and prior belief. The literature reveals large numbers of cognitive biases of which the following three are typical:

1. The rankism bias. According to (Fuller 2011), rankism is simply the idea that persons of higher rank in an organization are better able to assert their authority over persons of lower rank regardless of the decision involved. Rankism frequently occurs in aircraft cockpits. According to (McCreary et al. 1998), rankism was a factor in the famous Tenerife disaster.
2. The complacency bias. According to (Leveson 1995, pp. 54-55), complacency is the disregard for safety and the belief that current safety measures are adequate. According to (Leveson 1995, pp. 54-55), complacency played a role in the Three Mile Island and Bhopal disasters.
3. The optimism bias. According to (Leveson 1995, pp. 54-55), famous physicist Richard Feynman states that NASA “exaggerates the reliability of the system.” This is an example of the optimism bias.

Mitigation of Cognitive Bias

Various sources have suggested methods to mitigate the effects of cognitive bias. Following are some of the major ones.

1. Independent Review. The idea of independent review is that advice on decisions should come from an outside body, called by the Columbia Accident Investigation Board (CAIB) (NASA 2003, 227) as the Independent Technical Authority (ITA). This authority must be both organizationally and financially independent of the program in question. That is, the ITA cannot be subordinate to the program manager.
2. Crew Resource Management. Following a period of high accident rate, several airlines have adopted the crew resource management (CRM) method. The primary purposes of this method are first to assure that all crew members do their job properly and secondly that they communicate with the pilot effectively when they have a concern. The impetus for this method was the judgment that many pilots were experiencing the rankism bias or were preoccupied with other tasks and simple did not understand the concerns of the other crew members. The result is that this strategy has been successful, and that the accident rate has fallen.
3. The Premortem. (Kahneman 2011) (pp. 264-265) suggests this method of nudging in an organizational context. This method, like others, requires a certain amount of willingness on the part of the decision-maker to participate in this process. It calls for decision-makers to surround themselves with trusted experts in advance of major decisions. According to Kahneman the primary job of the experts is to present the negative argument against any decision. For example, the decision-maker should not authorize the launch now, perhaps later.

Requirements Management

- Lead Author:
- Tami Katz
- Contributing Authors:
- Lou Wheatcraft and Mike Ryan

-

Requirements management (RM) is performed to ensure alignment of requirements with other representations, analyses, and system artifacts generated across the life cycle. The scope of RM includes management of artifacts from the Concept Definition processes: Business or Mission Analysis and Stakeholder Needs Definition, as well as traceability to other systems engineering artifacts as described in System Requirements Definition process. RM includes providing an understanding of the requirements, an understanding of the needs from which they originated, establishing a baseline, communicating the needs and requirements, managing changes, providing status, and maintaining traceability with the rest of the artifacts of System Definition (INCOSE NRM 2022).

Purpose and Definition

As shown in Figure 1, RM is a cross-cutting series of activities that involve managing the sets of needs and the sets of design input requirements, including managing the needs and requirement definition activities, baselining the needs and requirements, communicating the needs and requirements, managing the flow down (allocation and budgeting) of requirements from one level to another, managing interactions (interfaces) both internal and external to the SoI, managing bidirectional traceability, and managing the design and system verification and validation artifacts, and managing change (INCOSE GtNR 2022).

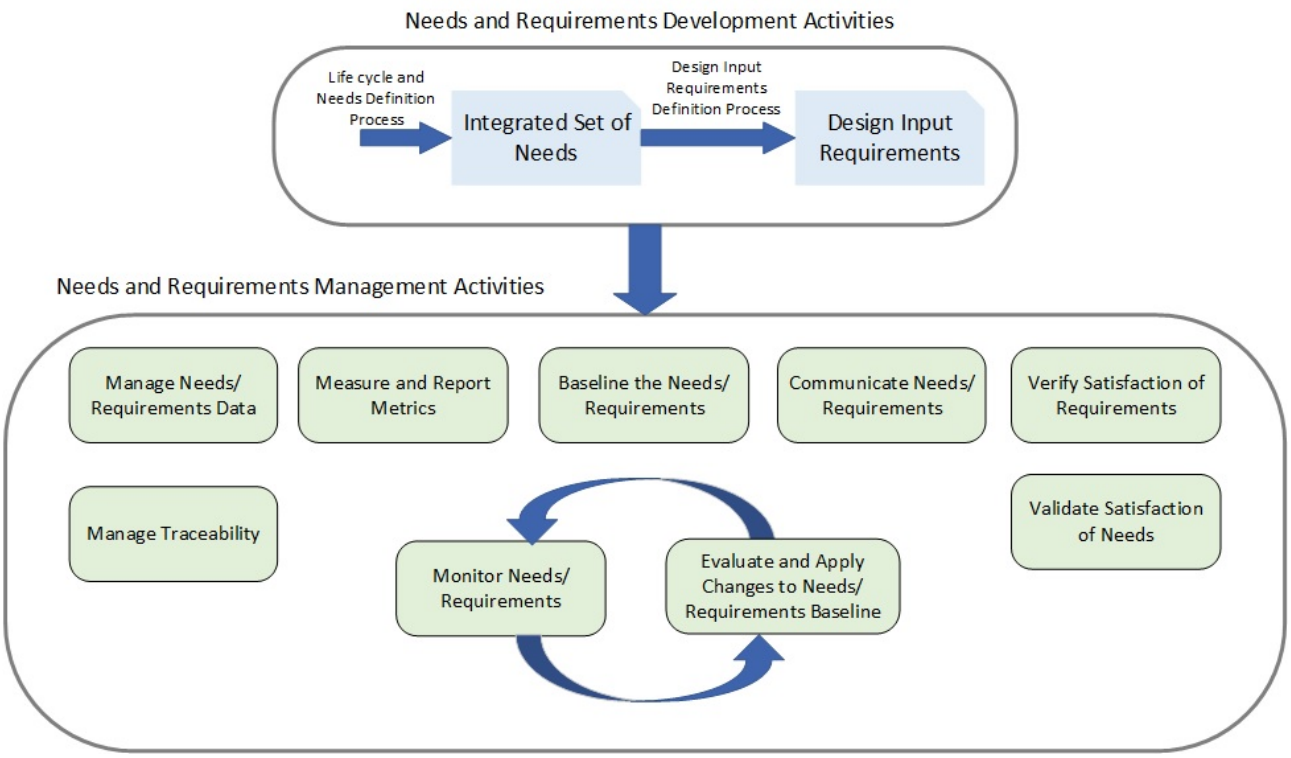

Figure 1. Requirements Management Activities. This figure is derived from the INCOSE Guide to Needs and Requirements v1, Figure 22, reprinted with permission of INCOSE. All other rights are reserved by the copyright owner.

While needs and requirements development addresses elicitation and creation of the needs and requirements as described in System Requirements Definition, the RM activities address how needs and requirements are managed across the project life cycle. These activities leverage other systems engineering management processes including Configuration Management (CM), Interface Management, Systems Analysis, and Information Management.

Process Approach

RM begins at the beginning of a project addressing the management of needs and requirements across the life cycle, ensuring the data and information from the development life cycle activities are captured, configuration controlled, and communicated. Enablers for RM include organizational processes, tools, and trained personnel in those processes and tools.

Configuration Management and Change Control

RM is closely tied to CM activities associated with baseline management and control of the sets of needs and requirements and other related artifacts. When the sets of needs and requirements have been defined, assessed, and approved, they are baselined. The baseline allows the project to define and manage budgets and schedules as well as analyze and understand the impact (technical, cost, and schedule) of any proposed changes.

There are several reasons needs and requirements could change:

- changing stakeholder needs, requirements, expectations,
- customer budget and schedule changes,
- emerging threats and risks,
- re-allocation of system performance, and
- changing operational environments.

Note that due to the iterative and recursive nature of SE across the life cycle there is an expectation of changes to needs and requirements, particularly early in the development life cycle, as requirements are allocated, budgeted, and requirements defined for lower-level architecture entities. This drives the need for an established change control process early in the effort.

Changes to needs and requirements can include modifications, additions, or deletions. Once a need or requirement is baselined, changes must include rationale why the change is necessary, which helps with impact assessment of the change. Impacts could include the cost of making changes at multiple levels in the architecture hierarchy (including suppliers), as well as the cost/schedule/technical impacts associated with any work-in-process updates (design, verification, etc.). Impacts to related needs, requirements, and interfaces also need to be considered when making changes. Traceability, described below, is a powerful enabler to support assessment and impact of need and requirement changes.

Monitoring and Control

The monitoring process uses the Measurement process to enable situational awareness of the status and quality of the RM process activities, including status of needs and requirement definition activities, incorporation of changes, and progress towards obtaining objective evidence during System Verification and System Validation that the needs and requirements have been met.

Controlling the needs and requirements involves actions taken to ensure the integrated set of needs reflect the life cycle concepts, MGOs, and measures from which they were derived, and that the requirements continue to address the intent of the integrated set of needs from which they were transformed. Monitoring and controlling also includes resolving unknowns (To Be Resolved (TBR), To Be Determined (TBD), etc.), addressing the quality and correctness of the needs and requirements, and managing changes to the needs and requirements.

Several types of metrics can be used as part of Monitoring and Controlling:

- number of needs,
- number of requirements,
- number of needs and requirements with TBDs or TBRs
- needs and requirements not traced to a source,
- status of system verification, and
- status of system validation,

The project must define which metrics will be used to monitor and control the needs and requirements as well as choose tools that enable these metrics to be defined and managed as well as tools that can communicate these metrics to the project team. The ability to monitor these metrics is supported through the use of attributes that provide additional content for the need or requirement. Example attributes to support requirements management include Rationale, Status, Criticality, Priority, Stability, and Responsible Person or Owner. Reference System Requirements Definition for more details on defining attributes.

Requirement Management Tools

There are many tools available to provide a supporting infrastructure for needs and requirements management; the best choice is the one that matches the needs and processes of the project or enterprise. Desired capabilities and features of RM tools include definition, collaboration, change control, and traceability to other project data (INCOSE NRM 2022). A requirements management tool (RMT) can enable a project's success by providing several capabilities:

- capturing the needs, requirements, and associated attributes,
- capturing requirement traceability to other data,
- communication of metrics and status,
- management of version control and changes, and
- facilitation of change impact analysis.

Modern RMTs vary in capabilities and costs. Pointers for finding various RMTs and other SE tools can be found in the Primary References section.

It is recommended that RMTs enable the sharing of data and information with other tools in the project toolset as part of a larger digital engineering ecosystem, as highlighted in Figure 2; this ability helps to maximize the ability to ensure consistency with other project data and artifacts generated across the life cycle, which is critical to being able to establish the Authoritative Source of Truth (ASoT) (INCOSE NRM 2022).

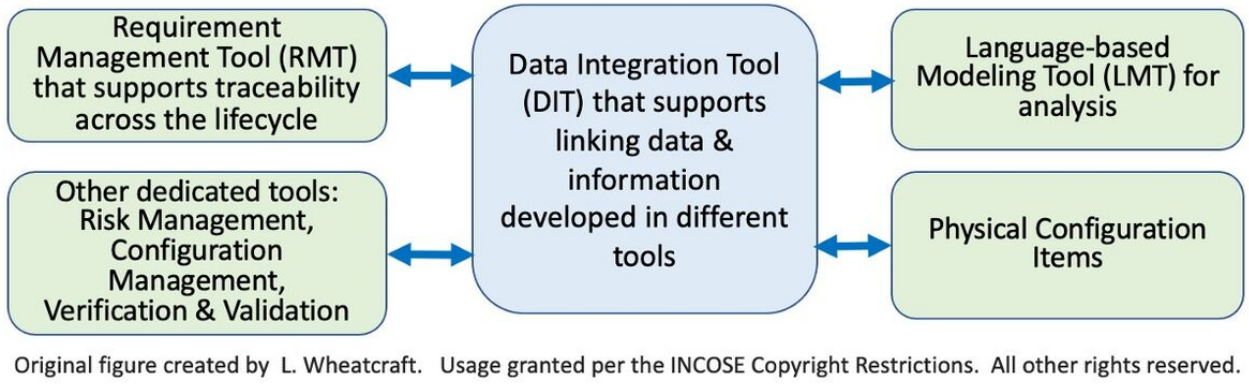

Figure 2. Requirement Management Tool as part of a Project's Digital Ecosystem. This figure is reprinted with permission of Lou Wheatcraft. All other rights are reserved by the copyright owner.

RMTs are most effective if they are setup with a common project schema, ontology, and templates, and team members are trained in their use before project initiation, ensuring the project team spends their time on the definition and management of needs and requirements and not on extensive development of the tool infrastructure.

Managing Traceability

As described in System Requirements Definition, traceability can be established between the needs and requirements and other sets of data and artifacts across the life cycle:

- operational Scenarios,
- risks,
- related requirements, and
- verification/validation artifacts.

RM processes are used to monitor traceability of data and ensure they are maintained over the system life cycle. This is enabled through use of toolsets that allow linkages of the needs and requirements to the other data within a digital ecosystem as shown in Figure 2.

Requirements Management Planning

The RM activities involve project resources and must be planned as part of the overall project and systems engineering planning efforts. A Requirements Management Plan (RMP) can be used to define and communicate scope and processes for managing needs and requirements across the SoI life cycle. An RMP keeps all team members and stakeholders on the same page. For smaller and less complex projects, the needs and requirements management process could be captured within the program or project management plan (PMP) or systems engineering management plan (SEMP). For larger and more complex projects, it is recommended a standalone RMP be developed.

There are several topics addressed within an RMP:

- Who will be responsible for the RM activities and deliverables?
- What tool(s) will be used?
- How will the project team interact with the stakeholders?
- What activities are involved in life cycle concepts and needs definition?
- What activities are involved in requirements definition?
- How will the needs and requirements be assessed for quality and correctness?
- How will changes be managed and controlled?
- What types of traceability will be used?
- What is the hierarchy of the sets of needs and requirements and how will it be managed?
- What attributes will be used?
- How will metrics need to be defined and reported?
- How are TBRs and TBDs managed?

Projects should plan for the RM approach based on the scale and complexity of the project and system to be developed and generate an RMP accordingly, and then update the plan if the processes evolve. Note that some projects are required to deliver their RMP to a customer, which may require additional content; however, do not generate a plan merely because a customer directed it, the development of an RMP is critical to project success. Proper planning can ensure desired outcomes when implementing an RM process.

Risk Management

- Lead Authors:
- Ed Conrow, Ray Madachy, and Garry Roedler
- Contributing Authors:
- Victor Bertolazzo, Leighton Johnson, Bob Parro, Jack Stein, and Richard Turner

-

The purpose of risk management is to reduce risks to an acceptable level before they occur, throughout the life of the product or project. Risk management is a continuous, forward-looking process that is applied to anticipate and avert risks that may adversely impact the project, and can be considered both a project management and a systems engineering process. A balance must be achieved on each project in terms of overall risk management ownership, implementation, and day-to-day responsibility between these two top-level processes.

For the SEBoK, risk management falls under the umbrella of Systems Engineering Management, though the wider body of risk literature is explored below.

Risk Management Process Overview

Risk is a measure of the potential inability to achieve overall program objectives within defined cost, schedule, and technical constraints.

The Risk Management Process section of the INCOSE Systems Engineering Handbook: A Guide for Systems Life Cycle Processes and Activities, 5th Edition, provides a comprehensive overview of risk management which is intended to be consistent with the Risk Management Process section of ISO 15288:2023. In this section of the INCOSE handbook two prominent risk concepts which may be encountered in a systems engineering project are discussed and tied to their respective internationally accepted definitions of risk (INCOSE 2023, pg. 84):

- The effect of uncertainty on objectives, see ISO/IEC/IEEE 15288, ISO 31073, ISO/IEC/IEEE 16085, ISO 31000, ISO 27000
- The combination of the probability of occurrence of harm and the severity of that harm, see ISO Guide 51, ISO 22367, ISO 14971

The first definition, which includes a note-to-entry stating that “effects may be negative or positive,” is different from the second in that the second definition accommodates only negative effects. Also, it is important to note that the first definition ties risks to specified objectives, while the second ties risks to identified types of potential harm without regard to objectives. Thus, the second definition is used extensively in safety engineering and in projects that require compliance to safety and risk management standards and regulations intended for the protection of public health, safety, and security.

A long-established approach to risk management is to identify and manage a set of individual risks for the project, while characterizing or expressing each individual risk as the combination of the following two components (DAU 2003a; INCOSE 2023, pg. 84-85):

1. the probability (or likelihood) of failing to achieve a particular outcome

2. the consequences (or impact) of failing to achieve that outcome

Among the benefits of this approach is that it supports the need for simple project risk metrics and familiar visual aids such the risk matrix (or risk cube). However, in practice, it is usually necessary to select and utilize a combination of various methods, techniques, and tools as deemed necessary. International standard ISO 31010:2019 *Risk management – risk assessment techniques* describes and provides guidance on selecting and applying 41 risk assessment techniques, including the risk matrix.

New techniques able to identify and better address undesirable outcomes associated with highly complex (and unpredictable) system behaviors, e.g., System Theoretic Process Analysis (STPA), are emerging and gaining international acceptance (SAE, 2025).

In the domain of catastrophic risk analysis, risk has three components: (1) threat, (2) vulnerability, and (3) consequence (Willis et al. 2005).

Risk management involves defining a risk management strategy, identifying and analyzing risks, treating selected risks, and monitoring the progress in reducing risks to an acceptable level (SEI 2010; DoD 2023; DAU 2003a; DAU 2003b; PMI 2021). The SE community, as a general rule, has recommended that "positive effects" of risks identified using the "effect of uncertainty on objectives" definition of risk be referred to as "opportunities". Opportunity and opportunity management is discussed in the "Opportunity and Opportunity Management" section below.

The SE risk management process includes the following activities:

- risk management planning
- risk identification
- risk analysis
- risk treatment
- risk monitoring

ISO/IEC/IEEE 16085 provides a detailed set of risk management activities and tasks which can be utilized in a risk management process aligned with ISO 31000, ISO 31073, and ISO 9001, which includes risk-based preventive action requirements.

Risk Management Planning

Risk management planning establishes and maintains a strategy for identifying, analyzing, treating, and monitoring risks within the project. The strategy, both the process and its implementation, is documented in a risk management plan (RMP).

The risk management process and its implementation should be tailored to each project and updated as appropriate throughout the life of the project. The RMP should be transmitted in an appropriate means to the project team and key stakeholders.

The risk management strategy includes as necessary the risk management process of all supply chain suppliers and describes how risks from all suppliers will be raised to the next level(s) for incorporation in the project risk process.

The context description for the risk management process should include a description of stakeholders' perspectives, risk categories, and a description (perhaps by reference) of the technical and managerial objectives, assumptions and constraints. The risk categories include the relevant technical areas of the system and facilitate identification of risks across the life cycle of the system. As noted in ISO 31000, the aim of this step is to generate a comprehensive list of risks based on those events that might create, enhance, prevent, degrade, accelerate or delay the achievement of objectives.

The RMP should contain key risk management information; Conrow (2003) identifies the following as key components of RMP:

- a project summary
- project acquisition and contracting strategies

- key definitions
- list of key documents
- process steps
- inputs, tools and techniques, and outputs per process step
- linkages between risk management and other project processes
- key ground rules and assumptions
- risk categories
- buyer and seller roles and responsibilities
- organizational and personnel roles and responsibilities

Generally, the level of detail in an RMP is risk-driven, with simple plans for low risk projects and detailed plans for high risk projects.

Risk Identification

Risk identification is the process of examining the project products, processes, and requirements to identify and document candidate risks. Risk identification should be performed continuously at the individual level as well as through formerly structured events at both regular intervals and following major program changes (e.g., project initiation, re-baselining, change in acquisition phase, etc.).

Conrow (2009) states that systems engineers should use one or more top-level approaches (e.g., work breakdown structure (WBS), key processes evaluation, key requirements evaluation, etc.) and one or more lower-level approaches (e.g., affinity, brainstorming, checklists and taxonomies, examining critical path activities, expert judgment, Ishikawa diagrams, etc.) in risk identification. The top and lower-level approaches are essential but there is no single accepted method — all approaches should be examined and used as appropriate.

Candidate risk management documentation should include the following items where possible, as identified by Conrow (2003 p.198):

- risk title
- structured risk description
- applicable risk categories
- potential root causes
- relevant historical information
- responsible individual and manager

It is important to use structured risk descriptions such as an *if-then* format: *if* (an event occurs--trigger), *then* (an outcome or affect occurs). Another useful construct is a *condition* (that exists) that leads to a potential *consequence* (outcome) (Gluch 1994). These approaches help the analyst to better think through the nature of the risk.

Risk Analysis

Risk analysis is the process of systematically evaluating each identified risk to estimate the probability of occurrence (likelihood) and consequence of occurrence (impact), and then converting the results to a corresponding risk level or rating.

There is no *best* analysis approach for a given risk category. Risk scales and a corresponding matrix, simulations, and probabilistic risk assessments are often used for technical risks, while decision trees, simulations and payoff matrices are used for cost risk; and simulations are used for schedule risk. Risk analysis approaches are sometimes grouped into qualitative and quantitative methods. A structured, repeatable methodology should be used in order to increase analysis accuracy and reduce uncertainty over time.

Once the risk level for each risk is determined, the risks need to be prioritized. Prioritization is typically performed by risk level (e.g., low, medium, high), risk score (the pair of max (probability), max (consequence) values), and

other considerations such as time-frame, frequency of occurrence, and interrelationship with other risks (Conrow 2003, pp. 187-364).

Widely used quantitative methods include decision trees and the associated expected monetary value analysis (Clemen and Reilly 2001), modeling and simulation (Law 2007; Mun 2010; Vose 2000), payoff matrices (Kerzner 2009, p. 747-751), probabilistic risk assessments (Kumamoto and Henley 1996; NASA 2002), and other techniques. Risk prioritization can directly result from the quantitative methods employed. For quantitative approaches, care is needed in developing the model structure, since the results will only be as good as the accuracy of the structure, coupled with the characteristics of probability estimates or distributions used to model the risks (Law 2007; Evans, Hastings, and Peacock 2011).

Descriptions and application guidance for a number of the above mentioned, as well as additional, risk assessment methods and techniques, may be found among the 41 contained in ISO 31010. Depending on the project environment and objectives, it may be beneficial to devote resources to researching, developing, and staying abreast of new and emerging analysis and assessment methods, techniques, and tools.

Risk Treatment

Risk treatment is the process that identifies and selects options and implements the desired option to reduce a risk to an acceptable level, given program constraints (budget, other resources) and objectives (DAU 2003a, 20-23, 70-78).

The risk treatment strategy selected is the combination of the most desirable risk treatment option coupled with a suitable implementation approach for that option (Conrow 2003). Risk treatment options include assumption, avoidance, control (mitigation), and transfer. All four options should be evaluated and the best one chosen for each risk. An appropriate implementation approach is then chosen for that option. Hybrid strategies can be developed that include more than one risk treatment option, but with a single implementation approach.

Additional risk treatment strategies can also be developed for a given risk and either implemented in parallel with the primary strategy or be made a contingent strategy that is implemented if a particular trigger event occurs during the execution of the primary strategy. Often, this choice is difficult because of uncertainties in the risk probabilities and impacts. In such cases, buying information to reduce risk uncertainty via prototypes, benchmarking, surveying, modeling, etc. will clarify risk treatment decisions (Boehm 1981).

Risk Monitoring

Risk monitoring is used to evaluate the effectiveness of risk treatment activities against established metrics and provide feedback to the other risk management process steps. Risk monitoring results may also provide a basis to (a) update risk treatment plans (RTPs), and/or the appropriate part(s) of the RMP, and (b) develop additional risk treatment options and approaches, and re-analyze risks. In some cases, monitoring results may also be used to identify new risks, revise an existing risk with a new facet, or revise some aspects of risk management planning (DAU 2003a, p. 20). Some risk monitoring approaches that can be applied include earned value, program metrics, technical performance measures (TPMs), schedule analysis, and variations in risk level. Risk monitoring approaches should be updated and evaluated at the same time and WBS level; otherwise, the results may be inconsistent.

Opportunity and Opportunity Management

In principle, opportunity management is the duality to risk management, with two components: (1) probability of achieving an improved outcome and (2) impact of achieving the outcome. Thus, both should be addressed in risk management planning and execution. In practice, however, a positive opportunity exposure will not match a negative risk exposure in utility space, since the positive utility magnitude of improving an expected outcome is considerably less than the negative utility magnitude of failing to meet an expected outcome (Canada 1971; Kahneman-Tversky 1979). Further, since many opportunity-management initiatives have failed to anticipate serious side effects, all

candidate opportunities should be thoroughly evaluated for potential risks to prevent unintended consequences from occurring.

In addition, while opportunities may provide potential benefits for the system or project, each opportunity pursued may have associated risks that detract from the expected benefit. This may reduce the ability to achieve the anticipated effects of the opportunity, in addition to any limitations associated with not pursing an opportunity.

Integrated Risk Management (IRM) and Linkages to Other Systems Engineering Management Topics

Per ISO 31000:2018, “integrating risk management with all organizational processes improves the performance of risk management while gaining efficiencies”. Clause 7 of ISO/IEC/IEEE 16085:2021 provides a methodical approach for the integration of risk management and “risk-based thinking” into all systems engineering life cycle processes.

Within Systems Engineering Management the practices of IRM and establishing linkages between risk management and other SE life cycle processes has been an area of interest for a number of decades. For example: The measurement process provides indicators for risk analysis. Project planning involves the identification of risk and planning for stakeholder involvement. Project assessment and control monitors project risks. Decision management evaluates alternatives for selection and treatment of identified and analyzed risks. With respect to linkages and interrelationship between systems engineering and project management, considerable work is documented the PMI-INCOSE-MIT collaborative Wiley book publication *Integrating Program Management and Systems Engineering: Methods, Tools, and Organizational Systems for Improving Performance*, (Rebentisch 2017).

Practical Considerations

Key pitfalls and good practices related to systems engineering risk management are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in performing risk management are below in Table 1.

Table 1. Risk Management Pitfalls. (SEBoK Original)

Name	Description
Process Over-Reliance	• Over-reliance on the process side of risk management without sufficient attention to human and organizational behavioral considerations.
Lack of Continuity	• Failure to implement risk management as a continuous process. Risk management will be ineffective if it's done just to satisfy project reviews or other discrete criteria. (Charette, Dwinnell, and McGarry 2004, 18-24 and Scheinin 2008).
Tool and Technique Over-Reliance	• Over-reliance on tools and techniques, with insufficient thought and resources expended on how the process will be implemented and run on a day-to-day basis.
Lack of Vigilance	• A comprehensive risk identification will generally not capture all risks; some risks will always escape detection, which reinforces the need for risk identification to be performed continuously.
Automatic Mitigation Selection	• Automatically select the risk treatment mitigation option, rather than evaluating all four options in an unbiased fashion and choosing the “best” option.

Sea of Green	• Tracking progress of the risk treatment plan, while the plan itself may not adequately include steps to reduce the risk to an acceptable level. Progress indicators may appear “green” (acceptable) associated with the risk treatment plan: budgeting, staffing, organizing, data gathering, model preparation, etc. However, the risk itself may be largely unaffected if the treatment strategy and the resulting plan are poorly developed, do not address potential root cause(s), and do not incorporate actions that will effectively resolve the risk.
Band-Aid Risk Treatment	• Treating risks (e.g., interoperability problems with changes in external systems) by patching each instance, rather than addressing the root cause(s) and reducing the likelihood of future instances.

Good Practices

Some good practices gathered from the references are below in Table 2.

Table 2. Risk Management Good Practices. (SEBoK Original)

Name	Description
Top Down and Bottom Up	• Risk management should be both “top down” and “bottom up” in order to be effective. The project manager or deputy need to own the process at the top level, but risk management principles should be considered and used by all project personnel.
Early Planning	• Include the planning process step in the risk management process. Failure to adequately perform risk planning early in the project phase contributes to ineffective risk management.
Risk Analysis Limitations	• Understand the limitations of risk analysis tools and techniques. Risk analysis results should be challenged because considerable input uncertainty and/or potential errors may exist.
Robust Risk Treatment Strategy	• The risk treatment strategy should attempt to reduce both the probability and consequence of occurrence terms. It is also imperative that the resources needed to properly implement the chosen strategy be available in a timely manner, else the risk treatment strategy, and the entire risk management process, will be viewed as a “paper tiger.”
Structured Risk Monitoring	• Risk monitoring should be a structured approach to compare actual vs. anticipated cost, performance, schedule, and risk outcomes associated with implementing the RHP. When ad-hoc or unstructured approaches are used, or when risk level vs. time is the only metric tracked, the resulting risk monitoring usefulness can be greatly reduced.
Update Risk Database	• The risk management database (registry) should be updated throughout the course of the program, striking a balance between excessive resources required and insufficient updates performed. Database updates should occur at both a tailored, regular interval and following major program changes.

-

Configuration management (CM) helps teams keep track of changes to a system over its life cycle—ensuring that what's built matches what was planned, and that everyone stays aligned as updates occur. Simply put, CM is about maintaining a clear, accurate picture of a system as it evolves—tracking changes, managing versions, and avoiding confusion.

As stated in ISO/IEC/IEEE 15288 (6.3.5.1): The purpose of the configuration management process is to manage system and system element configurations over their life cycle. The INCOSE *SE Handbook* describes CM as a key technical management process, supported by defined roles, resources, and controls. In this article, we may refer to a "system" or "product" depending on the application of the CM process.

Fundamental Concepts

CM and main CM concepts are defined slightly differently according to the various standards. The objective of this article is to provide a general understanding of CM based on common and general principles, usually aligned with INCOSE *SE Handbook*, ISO 10007, and SAE EIA-649C standards. Before entering in the description of the CM process, it is important to define a few concepts (below).

Applicability

CM applies to any kind of system; any product or process can be considered a system. Therefore, CM addresses hardware, software, services, systems, and systems of systems with equal relevance, or any combination of the above. CM is applicable regardless of the complexity of the system in question.

CM applies throughout the entire life cycle of the system. CM applies to all system life-cycle models and development approaches, with adequate tailoring.

In addition, to master the configuration of a system of interest, the configuration of the associated enabling systems should also be taken into account.

Configuration, Configuration Items, and Configuration Information

The configuration refers to the interrelated functional and physical characteristics outlined in configuration information, as defined by ISO 10007. The system and its individual elements, which fall under Configuration Management, are known as Configuration Items. Their functional and physical characteristics constitute their configuration information.

Configuration information encompasses the comprehensive data necessary to describe and document Configuration Items throughout the entire system life cycle. This includes artifacts produced during the execution of the technical processes, such as requirement specifications, architecture descriptions, design descriptions, and user documentation, as referenced in ISO/IEC/IEEE 15289.

Configuration information is understood as structured and contextualized data related to the system and its artifacts. While data serves as the raw input, information represents the processed output that adds context, relevance, and purpose. The collective set of configuration information associated with a system encapsulates all pertinent elements needed to document its characteristics.

CM fundamental objectives

The objectives of Configuration Management (CM) are to provide means to guarantee consistency between the system and its configuration information, ensure the integrity and traceability of this information and its changes over time, and facilitate reproducibility. These three objectives collectively enable the capabilities to define, realize, transition, operate, maintain, and dispose of the system.

How do you distinguish Configuration Management (CM) from Information Management (IM)?

Configuration Management (CM) and Information Management (IM) processes are interconnected; however, CM focuses on the relevance of information related to the system and its evolution over time, while IM concentrates on the management of the information itself. This includes its generation, collection, validation, transformation, dissemination, and disposal, overseeing the entire life cycle of the information.

CM is concerned with the significance and applicability of information in relation to the specific system elements with which it is associated, referred to as configuration information. While all information can be managed, only configuration information is subject to configuration management.

The CM and IM processes are complementary and closely aligned with the objective of ensuring traceability.

Configuration Management System

To ensure the CM process activities, a dedicated Configuration Management system to enable and support CM.

Process Overview

The Configuration Management process relies on appropriate processes, resources, and controls, to establish and maintain an authoritative source of truth on system configuration.

The CM process consists of activities that are widely used in key standards and references, including ISO/IEC/IEEE 15288, SAE EIA 649, and ISO 10007. The names of these activities may differ through various norms and standards, and in this article, the terms used are:

- Configuration Management Planning and Management
- Configuration Identification
- Configuration Change Management
- Configuration Status Accounting

- Configuration Verification and Audit.

The benefits of using the CM process are maximized when all five activities are planned and executed. These activities are not strictly sequential; rather, they are interrelated and may be applied concurrently and iteratively as needed throughout the system life cycle.

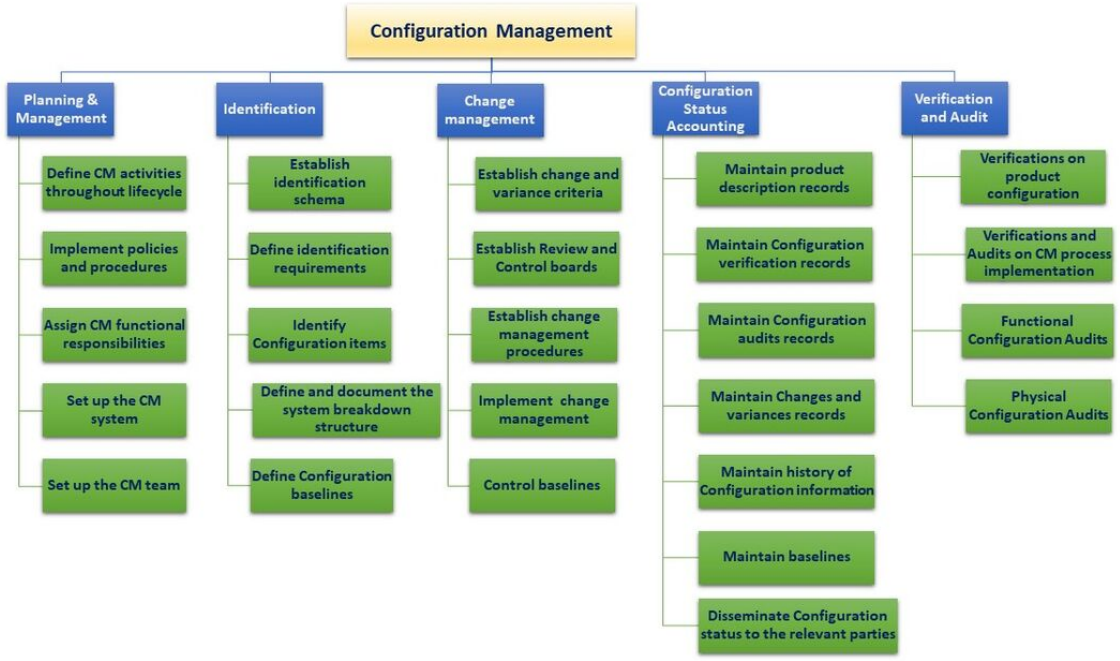

Figure 1. Configuration Management Activities (SEBoK Original)

CM Planning and Management

This first activity involves defining the scope and organization of CM tasks. It is considered good practice to formalize the results of this activity in a dedicated CM plan that guides implementation throughout the life cycle.

In terms of organization, the roles in charge of leading the Configuration Management activities on the project need to be defined early in the system life cycle. These roles constitute the CM team. This team is organized according to the size and complexity of the product to be managed and to the organizational rules of the organization. It should at least have a Configuration Manager, who oversees the CM plan.

CM Planning and Management defines the CM scope relevant for the system and for being able to maintain the consistency between the system and its configuration information: CM activities need to be adjusted to the type of system (hardware, software, service or combination of the above), the system life cycle, and to the system complexity, as well to the type of configuration information to be managed and to their criticality.

The activities depend also on the stages of the life cycle that need to be addressed as defined per contract: if all the stages of the life cycle must be managed from conception until retirement, the CM plan covers all these stages.

The CM plan should address the definition of the CM tasks, their organization, their schedule, the responsibilities of the various stakeholders of the system, and the tools to support the CM. CM activities involve most of the stakeholders of the system.

The CM plan should also be developed in consideration of the organizational context and culture. It must adhere to or incorporate applicable policies, procedures, and standards and it must accommodate acquisition, subcontracting and partnership situations, as well as any specific requirements agreements.

Except very specific use cases, CM planning and management should address the remaining activities as described hereafter.

Additional considerations about the Planning and Management of CM activities are provided in "CM implementation.

Configuration Identification

This activity overarches the following task:

- Identify which elements of the system and which information should be under configuration management
- Identify where configuration management is needed among the elements of the system: these elements are called "Configuration Items", the information related to these elements are their configuration information
- Define the identification rules for Configuration items and configuration information to apply to ensure the unicity, the rules to make these identifiers evolve, and the associated labelling constraints
- Structure the items and their information: this structure reflects the relationships between system items
- Define the rules for validating and releasing the items and the information under configuration management
- Define the baselines to be established at dedicated milestones of the system life cycle.

Note 1: a baseline specifies how a system is viewed for the purposes of management, control, and evaluation; each baseline is fixed at a specific point in time in the system life cycle and represents the current approved configuration; it serves as a basis for defining changes, and generally can only be changed through formal change procedures. See CM baselines for more details about typical CM baselines.

Note 2: depending on the practices and methods, the term "configuration item" may be used to designate anything that should be managed in the configuration management system, which leads to include the system elements and its information in the generic term "configuration items".

Configuration Change Management

A disciplined Configuration Change Management process is critical for engineering systems.

It encompasses the analysis, justification, evaluation, coordination and disposition of changes to the system and variances to the system (non-compliance to its requirements).

This activity aims to control the evolution of the system, of its elements and of its configuration information throughout the life cycle.

To ensure the missions of the activity, boards are defined to monitor and make key decisions regarding changes and variances process.

These boards are commonly called "Configuration Control Boards (CCBs)" but may also be referred to as "Configuration Steering Boards" or "Change Control Boards (CCBs)". They can also be split into Change Review boards and Change Implementation boards, when separately addressing the decisions about agreeing to the changes and variances and the stage where changes are implemented.

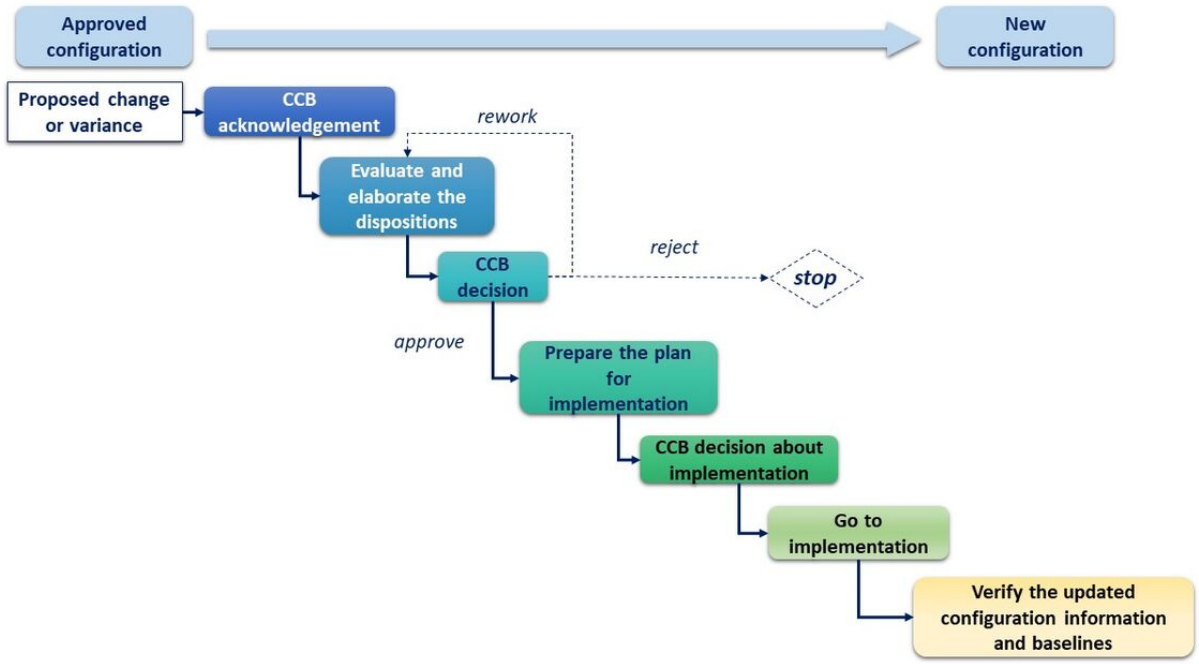

Figure 2. Example of decomposition of the CCB process (SEBoK Original)

A Configuration Control Board (CCB) typically includes:

- a CCB Chair,
- a Configuration Manager,
- the product or organization systems engineer,
- domain-specific subject-matter experts (SMEs) such as for software or mechanical engineering, product support, and cyber resiliency,
- procurement and contracting specialists.

The CCB dealing with the CM of a dedicated system or product (product CCB) may invite periodic participation from specialized or outside SMEs, including representation from vendors and subcontractors; this however must be carefully managed to ensure that information-access restrictions (especially for competition-sensitive information) is not compromised.

Organizational CCBs may be organized at a wider level and address several systems, products, or product lines and they typically include information technology (IT) and cyber resiliency SMEs who may not be needed on product-focused CCBs.

More advanced considerations about the change management and the related boards are provided in CM implementation.

Configuration Status Accounting

This activity covers all the reporting tasks that aim to provide dedicated reporting about the configuration information and the CM activities. The reports can address a wide range of content, for various purposes: internal reports for the organization and for the internal stakeholders, external reports as part of the deliveries planned in the contract, certificates and conformity reports, etc.

Elaboration

Configuration Management is involved in the management and control of artifacts produced and modified throughout the system life cycle. It is therefore linked to system analysis, system detailed design definition, system realization, system deployment and use, system operation and product and service life management.

CM must also work in conjunction with other technical management processes. These include project planning, project assessment and control, decision management, risk management, information management, and measurement.

This includes CM application to the artifacts of all the other management processes (plans, analyses, reports, statuses, etc.).

Practical Considerations

Refer to CM implementation for detailed considerations about the practical implementation of CM according to context.

Key pitfalls and good practices related to systems engineering CM are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing CM are in Table 1.

Table 1. Configuration Management Pitfalls. (SEBoK Original)

Name	Description
Shallow Visibility	• Not involving all affected disciplines in the change control process.
Poor Tailoring	• Inadequate CM tailoring to adapt to the project scale, number of subsystems, etc.
Limited CM Perspective	• Not considering and integrating the CM processes of all contributing organizations including COTS vendors and subcontractors.
Insufficient CM Awareness	• Insufficient awareness and training of all affected disciplines
Lack of CM Plan	• Not organizing the CM activities and provision of the adequate resources and means
Insufficient CM Checks	• Not verifying CM implementation regularly

Good Practices

Some good practices gathered from the references are provided in Table 2 below.

Table 2. Configuration Management Good Practices. (SEBoK Original)

Name	Description
Cross-Functional CM	• Implement cross-functional communication and CM processes for software, hardware, firmware, data, or other types of items as appropriate.
Full Lifecycle Perspective	• Plan for integrated CM through the life cycle. Do not assume that it will occur as part of the program without explicit planning.
CM Planning	• Processes are documented in a single, comprehensive CM plan early in the project. The plan should be a (systems) CM plan. • Include tools selected and used.
Requirements Traceability	• Initiate requirements traceability at the start of the CM activity.
CCB Hierarchy	• Use a hierarchy of configuration control boards commensurate with the program elements.
Consistent Identification	• Software CI and hardware CI use consistent identification schemes.
CM Automation	• Configuration status accounting should be as automated as possible.

Configuration Baselines

- Lead Authors:

-

In systems engineering, a configuration baseline is a formally approved snapshot of a system's attributes at a specific point in its development. These baselines—such as the functional, allocated, and product baselines—serve as reference points that guide and control subsequent changes to the system. By establishing baselines, teams can ensure consistency, manage complexity, and maintain alignment with requirements throughout the system's life cycle. Configuration baselines are an important concept in the overall disciplines of Configuration Management.

Fundamental Concepts

Process Overview

The information of a Configuration item are assembled into Configuration baselines at certain points after or within in a life cycle stage, as a set of consistent and immutable information that serve as starting points for further changes.

Many types of baselines could be defined depending on the complexity of the system and desire to manage certain types of configuration changes at different levels of the organization. The differences between the information item in each baseline could be by information item type (specifications or descriptions), by information item associated with configuration items at different levels of the system hierarchy, or both.

The next subsection presents three main Configuration Management baselines that are focused on specifications and definition characteristics of the system: Functional Configuration Baseline (FBL), Allocated Configuration Baseline (ABL), and Product Configuration Baseline (PBL). These three formal baselines contain different specifications and description information. They are usually generated in order and aligned with life cycle stage events. They are present in most norms and standards, with some variation in their names, definitions, and scope.

Each of these baselines generally have specific related ‘configuration documentation’: Functional Configuration Documentation (FCD), Allocated Configuration Documentation (ACD), and Product Configuration Documentation (PCD). Configuration baselines and Configuration documentation are crucial in managing the complexity of systems and products, ensuring that all components and configurations are well-documented and understood throughout the lifecycle of the project or product.

Other predefined baselines may exist for the CM of the system, either requested by the applicable normative context, defined in the Configuration Management Plan for specific project’s needs, etc. For example, Mission Objective Baseline which focuses on the purpose, constraints, environment and expected capabilities of the system as planned in [ECSS-M-ST-40C].

Finally, it is important to note that the content of the baselines or related configuration documentation is not necessarily limited to physical documents; the information can also include digital artifacts, such as models, databases, files, and more.

Functional, Allocated and Product baselines and documentation

The following provides definitions of the FBL, ABL and PBL baselines and FCD, ACD and PCD, whose detailed description may differ through various standards.

- **Functional baseline** represents the approved originating set of performance requirements for the system (functional, interoperability, and interface characteristics) and the verification required to demonstrate the achievement of those specified characteristics.
- **Functional Configuration Documentation:** includes information on the functional requirements, interface descriptions, and any changes made to the system over time.It serves as a reference for understanding the system's configuration and for evaluating changes or updates to its functionality. **Comparison:** the functional baseline acts as a foundational reference point, functional configuration documentation may evolve throughout the life cycle stages as design details are finalized and changes are documented.
- **Allocated baseline** represents the "allocation" of requirements to the major elements of the system (lower levels Configuration Items). It is the reference point for the functional and performance requirements that have been assigned. It defines what is expected from each component in terms of functionality and performance.
- **Allocated Configuration Documentation:** it details the specific configurations of the individual system elements that have been derived from the overall system requirements outlined in the allocated baseline. It may include design specifications, performance criteria, and how each system element is configured to meet its designated functions. **Comparison:** The allocated baseline is a conceptual framework or reference point, while the allocated configuration documentation is a detailed artifact that documents the specifics of individual system elements configurations.
- **Product baseline** gathers the approved definition and description information resulting from the system definition activities (e.g., system design definition).
- **Product Configuration Documentation:** This documentation provides comprehensive details about the configuration of a specific product, encompassing its physical and functional characteristics. It typically includes information about the product's design, elements, versions, and any configuration settings that are relevant. It describes how the product should be built and what specifications must be met. **Comparison:** The product baseline is an established reference for the overall product's characteristics, while the product configuration documentation contains the specific details needed to implement those characteristics.

Figure 1 hereunder provides a schema of the interconnections between the FBL, ABL and PBL baselines and associated documentation. It may vary according to the normative standard to be applied. In this figure, the terms 'Product Configuration Information' and 'Product Definition Information' are consistent with SAE-EIA 649C. The organizations may choose other terms.

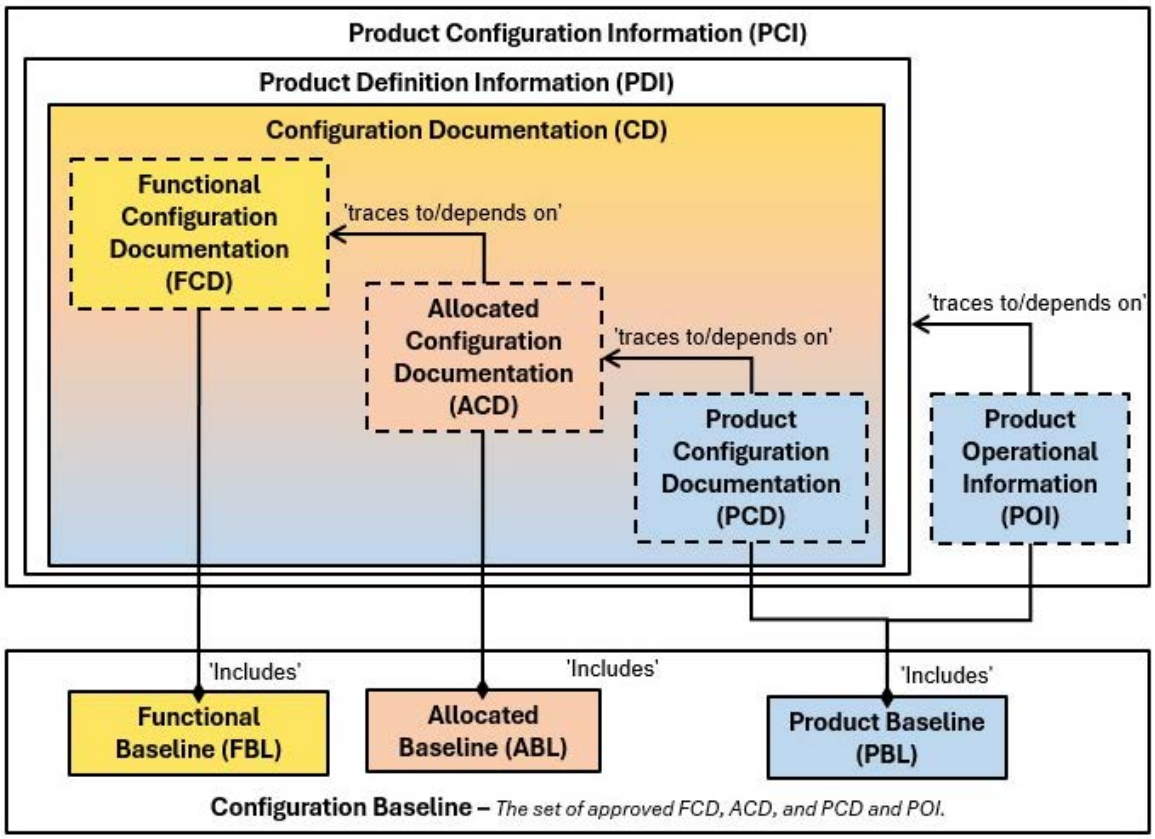

Figure 1. Relationships between configuration information and their configuration baselines as defined by EIA 649. (Copyright 2025 The MITRE Corporation, Used with Permission)

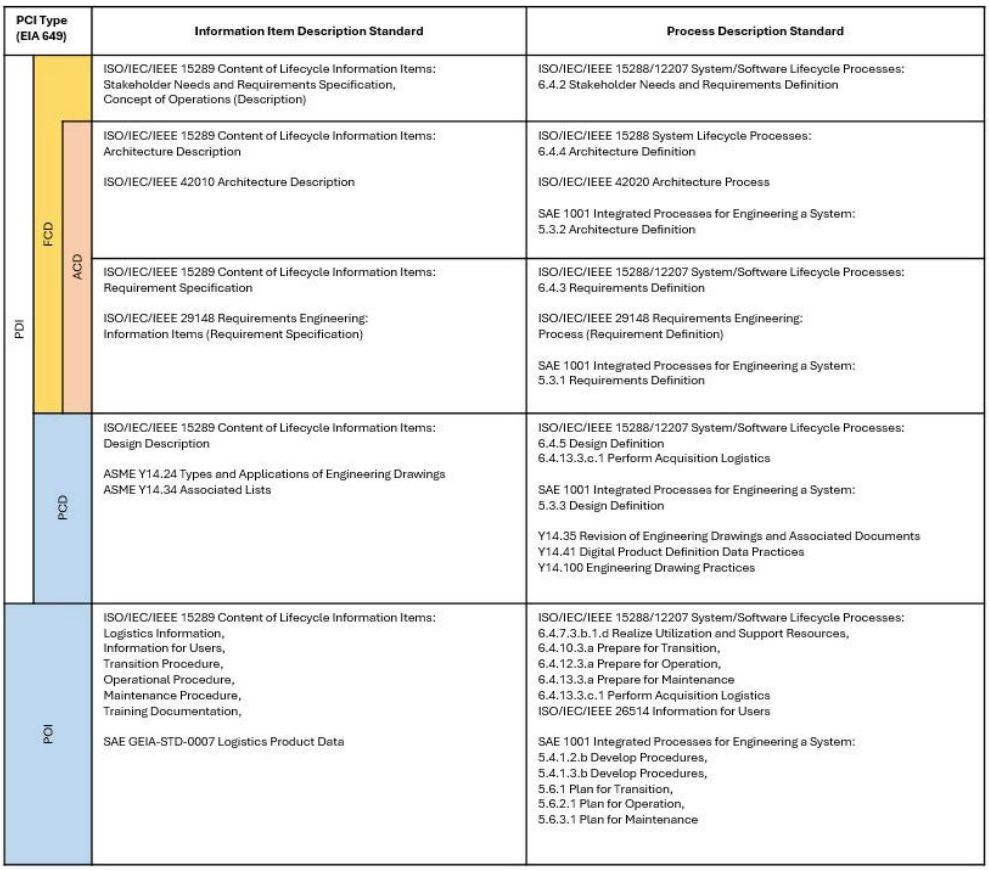
Figure 2 provides a description of the process and information standards related to product configuration information as illustrated in figure 1.



PCI Type (EIA 649)	Information Item Description Standard	Process Description Standard

Figure 2. Relationships between prominent configuration information and process description standards.

Elaboration

Configuration Management baselines are related to the artifacts produced and modified throughout the system life cycle. Baselining activities are therefore interfacing with system analysis, system detailed design definition, system realization, system deployment and use, system operation and product and service life management.

Practical Considerations

Pitfalls

Some of the key pitfalls encountered in Configuration baselines are in Table 1.

Table 1. Configuration baselines Pitfalls. (SEBoK Original)

Name	Description
Shallow Baselines Visibility	• Not involving all affected disciplines in baselines preparation and validation
Baselines needs are not tailored adequately	• Insufficient CM tailoring to adapt the baselines needs to the specific context of the project and to the system
Lack of Baselines planning and management	• Not planning baselines at the adequate milestones, not identifying rules for their validation and release
Baselines not used by the stakeholders	• Insufficient awareness of all stakeholders about the consideration of baselines as key references across the whole project
Missing Baselines checks	• Not verifying CM baselines regularly

Good Practices

Some good practices gathered from the references are provided in Table 2 below.

Table 2. Configuration baselines Good Practices. (SEBoK Original)

Name	Description
Cross-Functional Baselines	• Define baselines across the whole system, for software, hardware, firmware, data, or other types of items as appropriate
Baselines over the full lifecycle	• Define the baselines needed throughout the entire life cycle
Baselines Planning	• CM plan describes the needs in terms of baselines
Baselines tooling	• CM tools provide the adequate means to create, validate, and disseminate baselines
Baselines immutability	• CM baselines should be immutable reference points that serve as starting points for further change

Configuration Management Implementation

- Lead Authors:
- John Metcalf, Philip Hallenbeck, and Sandrine Gonthier
- Contributing Author:
- Garry Roedler

-

Implementing Configuration Management (CM) is about putting theory into practice—establishing the processes, tools, and responsibilities needed to manage changes to a system effectively. This involves planning how CM will function within an organization, defining roles, selecting appropriate tools, and integrating CM activities into the broader systems engineering workflow. By thoughtfully implementing CM, organizations can ensure that system changes are tracked, controlled, and communicated, maintaining the integrity and consistency of the system throughout its life cycle. This article is a compliment to Configuration Management.

Process Overview

As described Configuration Management, CM is a process that relies on appropriate practices, methods, and controls to provide the means to establish and maintain a source of authoritative data on system configuration.

This article provides guidance on how to plan the implementation of CM activities with a focus on explaining what elements to consider adapting CM to the dedicated context of the system to be addressed.

Principles and Concepts

Essential Areas to Evaluate for Adjustments

Product Information to be Considered in CM

The Configuration information should encompass product operational information and should not be limited to product definition information (see recommendation from the EIA-649C standard paragraph 5.2.2). Starting from the initial source of information provided by the document describing the operational conditions of the product, information about the product's physical environment of use, and the type of support to be provided in case of in-service support part of the contract, need to be considered.

Here are some examples of valuable product operation information: scope of use, user profiles, quantitative and qualitative requirements, etc.

CM Boards

The organization of CM activities is heavily influenced by the scope of the CM activities to be considered, and by the organizational factors addressed below. In general, complicated and critical products are managed by larger, more comprehensive CM organizations. Conversely, large organizations similarly require more comprehensive CM organizations and processes to manage the workload of key personnel.

Some considerations include the following:

Single CCB for Small Organizations

Small organizations, or those managing relatively simple products, may decide to have a single CCB staffed and operated at the organizational level, controlling not only organizational level configurations, but those of its respective projects or products. This can be a useful cost-saving measure, but one whose benefits must be balanced against the time demands of CCB membership and necessary expertise—especially as products increase in number.

Additional Boards for Larger Organizations and/or for Complex Systems

Larger teams or organizations, or those managing products of significant complexity, may choose to institute a Technical Review Board (TRB) prior to the CCB.

The TRB's function is to ensure thoroughness and correctness of the information supporting each CCB decision. Its membership depends on the demands of the CM subject, but it typically includes the relevant representatives of the major disciplines involved in the project, and subject matter experts as per needed. The TRB should address in detail the investigations and the arbitrations (technical and non-technical ones) prior to CCB to prepare the synthesis of the proposed analysis with predefined solutions to be agreed on in CCB.

CM Augmentation

The CM team must adapt to the system's complexity; greater complexity requires more dedicated and structured CM resources to manage a volume of configuration information that is greater and more complex. It induces the need for a detailed and formalized implementation of CM tasks.

Additionally, the contribution of various stakeholders is essential in performing specific CM functions.

For instance, when evaluation the compliance of a complex system to its requirements in a Functional Configuration Audit (FCA) part of Configuration Verification and Audit activity, the assistance of test engineers and technical writers would be typically required. Status accounting activities on complex systems may require participation from domain experts per expertise area (such as mechanical engineers, radiation engineers, chemical engineers, …) to ensure the correctness of the process and its artifacts. Systems engineers should ensure that these are accounted for in technical planning, estimation, and resourcing.

CM Training

In general, CM training should adhere to the principle of training to the specific standard of the organization and its processes. Hence, trainers should use generic process areas and principles as a foundation and introduction, only, to their program and its implementation. Important considerations in CM training include:

- Ensure that all organizational stakeholders are trained to a minimum level of awareness to support the Configuration Management (CM) initiative and help prevent interruptions to the CM process.
- Check that all stakeholders take CM activities into account when scheduling meetings and other activities.
- Make sure that CCB members and contributors understand the CCB workflow and necessary documents. It's especially important for contributors, like project systems and software engineers, to contribute to properly preparing CCB artifacts, as this avoids wasting time during CCB meetings.
- Make sure that everyone knows the status accounting procedures and documents, along with those for verification and audits. These activities are often viewed as the most impactful by CM contributors in engineering, production, or support. Therefore, it's crucial to train engineering staff on CM audit procedures and their significance in verifying CM. Similarly, ensuring that all team members understand how to access status accounting documents and their relevance to their roles will help build support for the CM effort.

CM Organizational Legacy and Tailoring

A CM organization with a background in previous projects can leverage the legacy of earlier CM plans, tools, and standardized methods as a foundational reference for new projects. However, the Configuration Manager must ensure that the existing processes and infrastructure align with the specific needs of the current CM efforts. If adjustments are necessary, the practices must be appropriately tailored, and such tailoring should be justified.

Constraints and Guidance

Constraints affecting and guiding the CM process come from various sources.

There are a variety of sources for guidance on the development of a CM process. These include the ISO standards on system life cycle processes (refer to latest ISO/IEC/IEEE 15288 version) and configuration management guidelines (refer to latest ISO 10007 version), as well as the *Guide to The Software Engineering Body of Knowledge* (SWEBOK) (2024), and the CMMI for Development V1.3 (SEI 2010).

Policies, procedures, and standards set forth at corporate or other organizational levels might influence or constrain the design and implementation of the CM process.

Guidance should also come from the CM purpose that may differ according to the organizations and/or to the projects, which has a direct influence on the CM effort:

- lifecycle phases to be considered, (operational and maintenance phases included or not), safety, cyber-security, environmental scope included or not,
- specific acquirer processes to comply with
- specific interfaces with authorities to consider,
- agreement(s) with acquirers or suppliers containing provisions affecting the CM process
- tools and associated practices
- other processes used in system development in interface with CM process
- etc.

In all cases, the balance between CM scope and CM costs needs to be addressed.

Highly rigorous CM implementation implies activities, resources and planning, that need to be adjusted to the correct level of control needed for each product. Highly critical products with safety constraints will, for example, need potentially a higher level of Configuration information to be managed and a higher number of CM verifications. The increase of control induces an increase of the cost of CM activities. However, for any product, the dedicated normative expectations of the context will drive the minimum set of CM requirements to be applied.

Organizational Issues

Successful CM planning, management, and implementation requires an understanding of the organizational context for the design and implementation of the CM process and why constraints are placed upon it.

To plan a CM process for a project, it is necessary to understand the organizational context and the relationships among the organizational elements. CM interacts with other organizational elements, which may be structured in various ways. Although the responsibility for performing certain CM tasks might be assigned to other parts of the organization, the overall responsibility for CM often rests with a distinct organizational element or designated individuals that constitute the CM team (Bourque and Fairley 2014).

The following are some examples of elements to be considered for a dedicated project:

- size of the organization,
- budgets,
- schedules,
- contract requirements for CM,
- approval authority for the configuration,

- access and control of CM information, IT-security constraints,
- certification requirements,
- internal context: enterprise management system, processes, and supporting systems to achieve the CM activities,
- external context: Acquirer/Supplier CM interfaces with a contracted relationship to support external trusted interactions,
- IT infrastructure to provide an adequate CM management system supporting the requested CM activities.

Some examples of organizational elements to be considered across the entire organization (this is not an exhaustive list) include:

- IT needs to support the various CM management systems of the projects of the organization
- IT support teams to provide training and support for the usage of the CM tools
- Cyber-resiliency expectations, with the support of the relevant subject-matter experts (SMEs)
- IT infrastructure requirements:
  - Capacity to support the CM activities for all the projects of the organization
  - **Provision and status of backups**. While products of low complexity or criticality may be able to suffer a discontinuous CM tooling with little impact, complicated or safety-critical systems often require continuous access to CM info. Hence, IT may need to include CM tools and repositories in a hot or warm backup scheme.
  - **Traceability and preservation of the history** of all Configuration Information are part of the requirements for CM.
  - **Information hosting and access**. CM information is often proprietary and competition-sensitive and sometimes classified in accordance with national security requirements. Hence, both hosting and access must often be controlled.

Measurement

To carry out certain CM activities, such as status accounting, verification and auditing, as well as to monitor and assess the effectiveness of CM processes, it is necessary to measure and collect data related to CM activities and system artifacts.

CM management system and automated report tools provide convenient access and facilitation of data collection.

Measurement of CM effectiveness would concern address the assessment of CM strategy deployment and maturity, for example:

- are the CM processes clearly documented for all life cycle phases, planned, deployed, known, applied?
- are the stakeholders trained and aware of their involvement in CM activities?
- are the tools providing the adequate capabilities to ensure CM activities?

Measurement of CM performance could address the quantitative aspects of CM activities implementation:

- Volume of Configuration items to manage
- Volume of configuration information
- Volume and costs of changes
- Volume of variances
- Duration of impact analysis to assess the impact of changes and variances
- Time to approve a change, time to implement an approved change
- Proportion of rework of impact analysis (not aiming to decision in CCB at first attempt)
- Number of discrepancies detected in CM verifications
- Number of attempts to get Functional and Physical Configuration Audits successfully passed.

It must be noted that most quantitative measures of CM performance would indeed address the performance of all the disciplines involved in the CM activity:

- the time to perform an impact analysis is mainly illustrating the time needed by the various expertise and engineering stakeholders to evaluate all the induced impacts of a change
- the time to implement a change may be driven by the manufacturing or purchasing constraints that could delay the implementation to include it in a dedicated batch

Tools

CM employs a variety of tools to support the process, that may depend on the nature of the system under CM and of the nature of the system artifacts. In a very general way, the Configuration Management system relies on tools such as Product Lifecycle Management and Application Lifecycle Management applications, and it can be seen as a federated environment. This environment could encompass various functionalities, among which

- information management
- tracking and change management
- version management
- release management
- baseline management
- breakdown structures management.

Practical Considerations

Pitfalls

Some of the key pitfalls encountered in implementing CM are in Table 1.

Table 1. Configuration Implementation Pitfalls. (SEBoK Original)

Name	Description
Poor Tailoring	• Inadequate CM tailoring to adapt to the project scale, number of subsystems, etc.
CM Boards organization not clarified	• Missing a visible and detailed organization of the boards over the whole system
Insufficient CM training	• Insufficient training of all affected disciplines
Insufficient CM tooling	• Lack of tools supporting the CM tasks

Good Practices

Some good practices gathered from the references are provided in Table 2 below.

Table 2. Configuration Implementation Good Practices. (SEBoK Original)

Name	Description
CM activities adjusted to the project needs	• CM activities consider the context of the project, the characteristics of the system, and the context of the organization
CM Boards organization	• The various boards have been set up according to the project needs, and their organization is adjusted along the lifecycle when needed
CM Resources	• The CM team organization is anticipated
CM Tools	• The Configuration Management system is set up to guarantee adequate support to the CM tasks, and to alleviate the administrative tasks.
CM Training	• CM training is available all through the project with adequate content for the involved stakeholders' priorities

Information management (IM) helps teams access and manage information over its lifecycle, ensuring that the information is relevant, complete, verified, protected, distributed and managed. Simply put, IM is about maintaining a clear, accurate, and accessible picture of information to one or more audiences.

As stated in ISO/IEC/IEEE 15288 (6.3.6.1): 'The purpose of the Information Management process is to generate, obtain, confirm, transform, retain, retrieve, disseminate, and dispose of information to designated stakeholders'.

Fundamental Concepts

The INCOSE SE Handbook describes IM as the process that "plans, executes, and controls the provision of information to designated stakeholders that is unambiguous, complete, verifiable, consistent, traceable, and presentable".

The IM process ensures that necessary information is created, stored, retained, protected, managed, and made easily available to those with a need and who are permitted access. It also ensures that information is disposed of when it is no longer relevant.

The scope of information to be considered is wide, addressing technical, project, organizational, integration, contractual, agreement and user information, and any other information deemed relevant for the organization, all of these designated as 'information assets' in this article.

Effective IM enables business objectives, as illustrated in Table 1 below:

Table 1: IM Enables Business Objectives (SEBoK Original)

Objective	How is IM enabling the objective
Operational efficiency	Through organizing secured processes for the collection, access and distribution of the information
Support analytics and decision-making	Through managing, in a controlled way, the tangible and intangible information assets and preserving them against uncontrolled modifications, threats and loss (cybersecurity dispositions against digital threats, resilient storage structures and pre-defined disaster recovery dispositions)
Quality and security	Through managing, in a controlled way, the tangible and intangible information assets and preserving them against uncontrolled modifications, threats and loss (cybersecurity dispositions against digital threats, resilient storage structures and pre-defined disaster recovery dispositions)
Competitiveness and innovation	Through providing access to the crucial information needed to make decisions and through the capability to extract meaningful insights from information analysis
Compliance	Through planning the adequate dispositions and access controls to comply with legal requirements, intellectual property and regulations applicable to information and data

From a business enterprise perspective, the systems engineer, as well as many other stakeholders involved in systems development, may be involved in several activities that support the management of information across the enterprise and its projects. It may include strategic planning, analyses of technology/business trends, development of applications, understanding operational disciplines, analytics supporting decision-making, resource control techniques, and assessment of organization structures.

Information Versus Data

Terms like artifact, asset, work product, and documentation are commonly encountered in system engineering projects and are often used interchangeably to refer to **information** and **data** without regard to their difference.

ISO/IEC/IEEE 15289 describes **data** as outputs of life cycle processes that can be individually recorded and managed, composable into a structure set and treated as a unit called a **record**, and part of information items (documentation). **Information items** (documentation) *"are produced and communicated for human use and contain formal elements (such as purpose, scope, and summary), intended to make them usable by their intended audience".*

ISO/IEC/IEEE 15289 also describes the content for the general and specific information items that are inputs and outputs from life cycle processes. (Remark: U.S. DoD projects use MIL-STD-963C to describe the contents of information items).

Similarly, GEIA- STD-927B defines **data** as *"A representation of facts, concepts, or instructions in a formalized manner suitable for communication, interpretation, or processing by humans or by automatic means"* and **information** as "*Data organized in a form that can be interpreted by humans or computers.* Note: these definitions are *"frequently used to discriminate between uninterpreted measurements (data) and meanings derived from raw data through some form of analysis (information)".*

Data Management Body of Knowledge (DMBOK) acknowledges that **data** and **information** can be differentiated in a similar way if it will better enable communication within an organization. An example of these relationships is shown in Figure 1. Conversely, GEIA-STD-859B defines data as "information that has been recorded in a form or format convenient to move or process".

Figure 1 below shows examples of relationships between data and information items in a project. However, it should be noted that this figure only mentions a few examples of data and information items that may have a much broader scope in a project or organization.

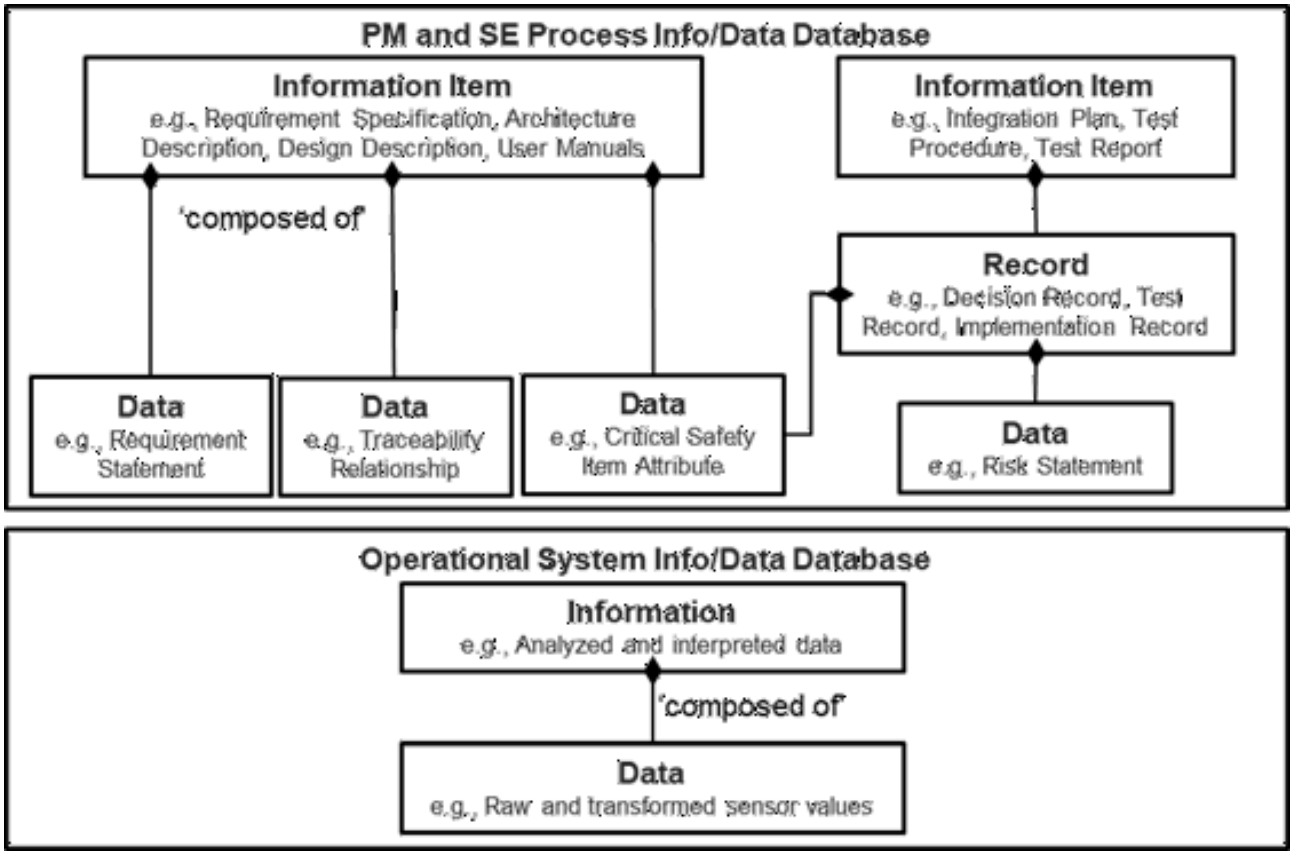

Figure 1 – Example of relationships between information and data encountered in System Engineering (SE), Project Management (PM), and System Operation. (SEBoK Original)

Using the above-mentioned standards, we can synthesize a convenient definition for information and data: **data are raw unstructured values, and information is structured data in context that has been analyzed and interpreted.**

Even though information and data are different, some organizations may choose not to differentiate between management of the two. The definitions, relationships, use, and management of PM, SE or Operational System information and data should be described in the project's management plans or system's configuration information, respectively.

Information Asset

An **information asset** is any piece or collection of information that must be managed independently.

The information items described by ISO/IEC/IEEE 15289 would be considered as information assets.

Information assets:

- can exist in many tangible or intangible forms in an organization,
- are either related to a specific system development project or held at enterprise level and made available to projects as required: e.g., Product Line Engineering information, generic procedures and processes,
- may be held in electronic format and/or in physical form: electronic or paper drawings or documentation, microfiche, photographic record, file, database…

Table 2 gives some examples of criteria that may be considered when choosing between formats:

Table 2: Electronic Format Versus Physical Format (SEBoK Original)

	Electronic Format	Physical Format
Pros	• Ease of access to various stakeholders • Searchability • Maintainability • Ease of multiple use enhanced by the capability to use links towards the information	• No need for access software • Long term storage • Robust to corruption and cyberthreats
Cons	• Potential for data corruption and cyberthreat-sensitive • Need to manage long term storage and archiving solutions • Need to manage the longevity of access software	• Less searchable • Access capabilities driven by physical locations • Long term preservation of the media depending on the physical support

Metadata

Metadata can be thought of as 'data about data.' It consists of 'data' that characterizes the information or data to be managed: for example, the title of the information, the author(s), the provenance, or the status of the information.

Metadata is particularly useful to organize the information database, to use the information and to search and navigate across the information database. It plays a key role in the organization of the governance of the information and data and contributes to quality and integrity objectives of the IM process.

Information Management versus Knowledge Management

According to SE HBK, **Knowledge Management** (KM) differs from Information Management (IM) as it is managed at Organization level and focused on providing the capability to re-apply existing knowledge.

However, KM is related to IM when it addresses explicit knowledge captured in information assets. Also, IM can be used to aid the objectives of KM by providing the means to manage the information regarding the knowledge assets.

Some examples of information assets, which may be considered as knowledge artifacts at the level of the organization, include:

- Technical content: leveraging and capitalizing on past engineering documentation, manufacturing processes, standard test procedures, design guides…
- Architectural and Design patterns
- Reusable content, i.e. product line information, generic analyses, previous documentation reusable pre-defined templates…
- Process information: process definition documentation, instructions, "How-to" guidance, validation information for analytical tools (e.g. aero-thermo-mechanical analysis tools).

How Does Information Management Relate to Configuration Management?

Information Management (IM) and Configuration Management (CM) are closely interconnected: whenever information assets correspond to identified Configuration Information related to systems or products under Configuration Management, those information assets should be subject to CM.

As noted in SEBoK Configuration Management article, 'CM is concerned with the significance and applicability of information in relation to the specific system elements with which it is associated, referred to as configuration information', while the IM process deals with the management of information itself over its own lifecycle: information generation, collection, validation, transformation, dissemination, and disposal.

The IM process is also complementary to CM to ensure the **traceability** of information in Configuration Management perspective.

Information Security Management

IM incorporates the fundamental need to manage the security of information assets.

Information security encompasses the mitigation of all kinds of breaches (digital and physical ones) that may expose personal, proprietary and industrial data, with associated consequences in terms of cost, image, and financial damages. It addresses a broader scope than cybersecurity, which focuses on electronic data, devices, and systems. It must consider all forms of storage, including information on physical formats and even knowledge held in the minds of stakeholders.

It must address the protection of intellectual property and trade secrets and comply with legal and regulatory requirements protecting privacy.

A simple approach for information security, inspired from the detailed methodology available in National Institute of Standards Special Publication 800-160v1r1, *Engineering Trustworthy Secure Systems*, should plan the 5 major steps explained below:

1 - Define Sensitive Information:

Determine the levels of Information sensitivity relative to pre-defined criteria, according to the nature of information to be managed and to the regulations and norms to comply with

Examples: information aiming to identify an individual, health information, national security information, or competition sensitive information.

2 - Define Data and Asset Classifications:

Define a global classification dictionary with clear classification rules, in accordance with the levels of sensitivity and considering the whole set of stakeholders along the system lifecycle; these rules should consider the variability that may exist in case of large systems involving many organizations and countries.

3 - Determine Information Security Controls, that may include the following:

· Information encryption, for both use-cases of information at rest (stored or archived) and under distribution, with considering the induced cost, processing, network and coordination overhead

· Digital signatures Distribution restrictions in accordance with the classification, enforced either by procedures or tools, including non-disclosure agreements (NDAs) between organizations, making them liable in case of disclosure of protected information

· User security education with regular refresher training and monitoring

4 - Implement Information Security Controls:

Ensure controls adapted to each sensitivity classification and to the phasing of the connections across organizations (either existing or under development), with the adequate planned tools and resources

5 – Monitor execution:

Ensure measures to provide insights and status about information security, taking advantage of existing cybersecurity dispositions when available.

Information Management System

A dedicated **Information Management system** is needed to enable and support the IM process and its activities.

The IM system must comply with the involved organizations' security policies along the full lifecycle of information assets.

A typical IMS includes capabilities to do or assist with the following functionalities:

- Collection and organization of data and information
- Storage and retrieval of both raw data and information
- Analysis of data to transform it into information
- Creation of relevant reports/reporting of the results per appropriate context for decisions
- Protection of data and information
- Management of the access rights, responsibilities and authorities over the information database
- Compliance with laws and regulations.

Engineering the Information Management System

The Information Management system (IMS) aims to ensure the functions identified in the previous section while guaranteeing information availability, reliability, provenance traceability, security.

The IMS stakeholders' range may address a wide scope: project management, cybersecurity, systems engineering, specialty engineering disciplines, configuration management, quality management, industry, service functions, ... across one or several organizations.

The life cycle processes can be used to engineer the IMS as the system in charge of answering to the organizational need to manage its information and data. An example of approach is shown in Figure 2:

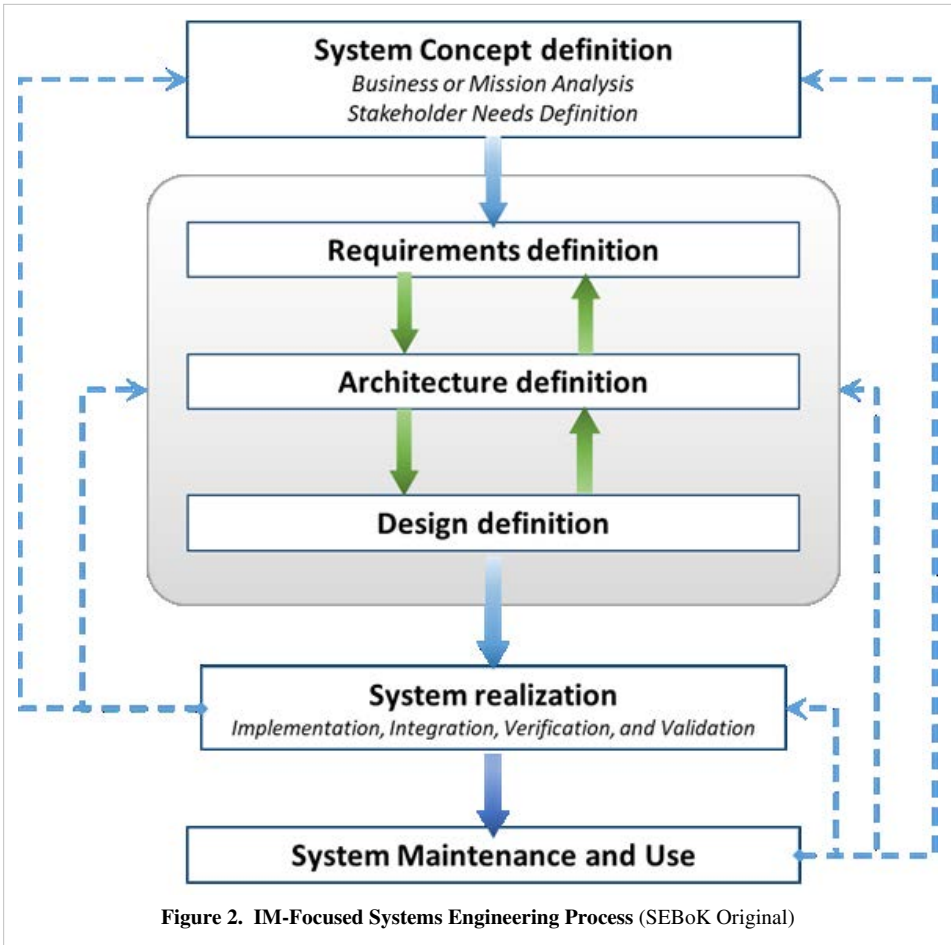

Figure 2. IM-Focused Systems Engineering Process (SEBoK Original)

Each major step in figure 2 includes several considerations of particular importance to IM:

- **In Concept Definition** (Business or Mission Analysis and Stakeholder Needs Definition):
  - The involved stakeholders and organizations and their needs in terms of access controls
  - The needs for security boundaries
  - The needs for audits
  - The applicable regulations, laws, protection requirements

    - The information lifecycle requirements per type of information
- **In Requirements Definition and System Architecture Definition**:
    - The existing structures and their constraints: repositories, cybersecurity architectures
    - The existing information and configuration management processes (including problem reporting and change management),
    - The existing syntax and semantics
    - The disaster recovery dispositions
- **In Design definition**:
    - Potential iterations when designing the IMS to consider changes to introduce new requirements for retrieval speed, archiving, metadata, data modelling, access rules
- **In Realization** (Implementation, Integration, Verification, and Validation)**:**
    - Incremental integration, verification, and validation of the IM system to enable a stepwise adoption of new processes
    - Application of information and configuration management rules
    - Involvement of stakeholders in tests to value their feedback
    - Coordination with IT and cybersecurity staff especially during initial implementation steps
- **In Maintenance and Utilization:**
    - Needs to adapt the information lifecycle, always controlled by dedicated processes (information and/or configuration management workflows)
    - Regular disaster recovery and retrieval plan exercise
    - Performance and quality monitoring of a dedicated set of indicators
    - Stakeholders' feedback to maintain their involvement in the overall IMS quality.

Process Overview

The IM process relies on a defined approach that includes appropriate practices, methods, procedures, resources, and controls to establish and maintain a reliable source of Information.

A decomposition is proposed below, inspired by the SE HBK IM section. Examples of decomposition could also be found in ISO/IEC/IEEE 15288 Clause 6.3.6, SAE 1001 Clause 5.2.5, ISO/IEC/IEEE 24748-7 Clause 6.3.6.

The benefits of the IM process are maximized when all activities are planned and executed. These activities are not sequential. They may be applied concurrently and iteratively as needed throughout the information life cycle.

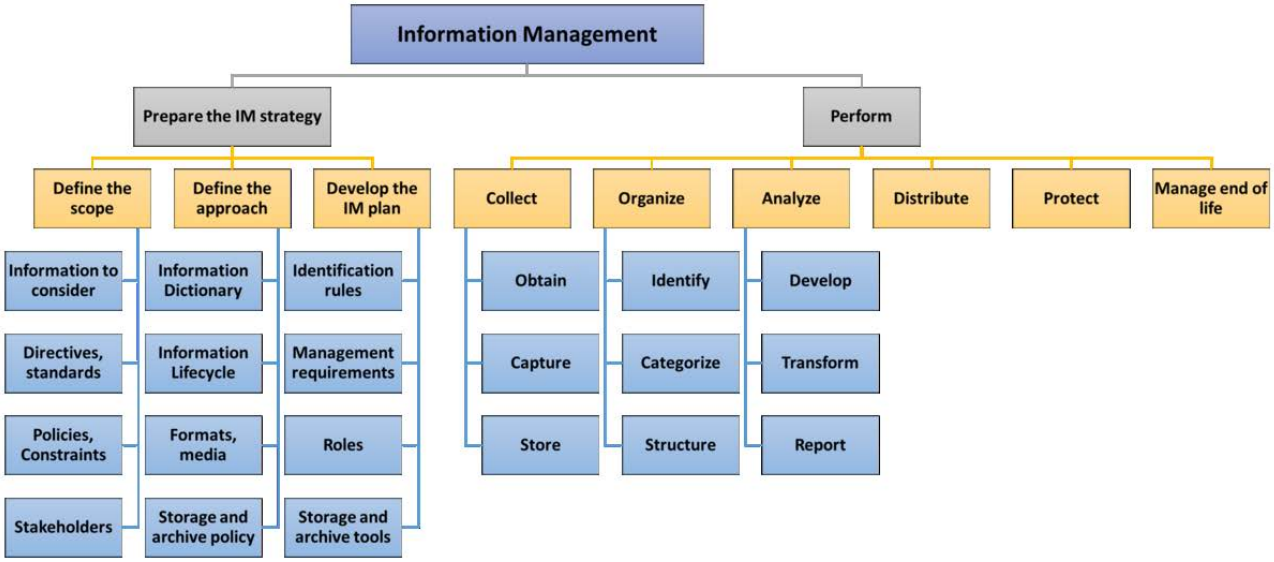

Figure 3. Information Management Process (SEBoK Original)

Here are some insights about the proposed sub-activities:

- **Prepare for information management** (preparing the information management strategy):
  - Define the scope:
    - Relevant information and valid sources to be considered (business processes which will provide information)
    - Directives, standards to be considered, including customers' requirements, industry standards…
    - Policies, constraints: organization internal policy and directives, external constraints (e.g. legal, environmental, geographical, regulations)
    - Stakeholders
  - Define the approach:
    - Information dictionary to consider the information to be managed (may be related to the project planning outputs in case of a system's information)
    - Information lifecycle:
      - Stages and status of the information asset, from initialization until obsolescence and disposal
      - Transition triggers between the lifecycle stages, defining workflows
      - Change process to control the evolutions of the information, and when relevant, the traceable incorporation in Configuration Management baselines
      - Authorized formats for capture, retention, transmission, retrieval, distribution
    - Requests for adequate repositories and tools
    - Storage and archive policy: retention duration, end of life disposal process, disaster recovery dispositions to prevent the loss of information in case of failure (back-up system, flawless recovery plan)
  - Develop the IM plan:
    - Identification rules: identification schema, mandatory attributes and metadata aiming to ease of search, rules for identifiers evolution
    - Management requirements
      - applicable to information capture, storage, validation, release, retrieval, and distribution

    - problem reporting and change management, for both configuration information and information out of configuration scope
    - control and security rules per type of Information, e.g. export control, access or distribution control, Intellectual Property, segregation of information between projects…
    - auditing capabilities on the information database
  - Roles
    - Responsibilities: roles providing, managing, consuming, distributing information (including external distribution to suppliers, customers, partners)
    - Authorities: roles in charge of IM policy and governance inside the organization, roles defining the IM system requirements…
  - Storage and archive tools, consistent with the policy identified in the approach
- **Perform information management**
  - Collect the information: obtain from the valid sources, capture and store according to the IM plan
  - Organize the information: identify and categorize, structure the information to identify their relationships with the system's elements to which they are related
  - Analyze: develop or transform the information, report about the information to support decision-making
  - Distribute the information to designated stakeholders inside the organization and to the relevant external stakeholders in accordance with predefined processes
  - Protect the information: maintain integrity, security, privacy, in accordance with the applicable requirements
  - Manage end-of-life: control information obsolescence, identify obsolete information and assess whether it should be archived or disposed of; it aims to prevent the uncontrolled growth of the information asset database by retaining content that should be archived or destroyed in accordance with applicable policies or agreements.

Elaboration

Information Management is involved in the management and control of artifacts produced and modified throughout the system life cycle and across the organization.

The list of types of information assets to be managed and their cadence in the systems engineering and project lifecycle should be defined in the planning process and documented in the IM plan. For information assets related to configuration management, their cadence should be consistent with CM requirements.

The IM process is therefore linked to configuration management, project planning, project assessment and control, system analysis, system detailed design definition, system realization, system deployment and use, system operation and service life management.

Practical Considerations

Key pitfalls and good practices related to IM are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing IM are provided in Table 3:

Table 3. Information Management Pitfalls. (SEBoK Original)

Pitfall Name	Pitfall Description
No Information / Data Dictionary	Not defining an information/data dictionary for the organization or for the project may result in inconsistencies in identification conventions for information, which reduces the accuracy and completeness of searches for information and adding search time performance.
No Information identification strategy	Not specifying the naming convention for information and identification rules may result in inconsistent information identification, difficulties to retrieve information and impossibility to ensure consistency of the information across the whole project or organization
No Metadata	Not defining the relevant metadata per type of information or tagging them inconsistently may result in ineffective searches based on metadata which are ineffective and can overlook key information.
No predefined Information / data lifecycle	Missing definition of the information lifecycle defining creation and validation workflow, release mechanism, obsolescence management, leading to uncontrolled creation and validation of information, overaccumulation of obsolete data
No security rules	Not defining the security classification levels nor the associated security protection mechanisms induce quickly high levels of risks of information leaks that could engage the legal responsibility of the organization
No clear information communication rules	Not defining the conditions for reception and distribution of information leads to lacks in traceability. Information should be considered as key assets and their communication across the stakeholders need to be organized
Missing content-obsolescence management	Not checking the currency and relevance of the information content, and not tagging obsolescent and obsolete information results in outdated information being retained and used inadequately, and induces an overload in the storage capacity needs
Missing access-obsolescence management	Not checking the currency and relevance of the access rights could lead to maintaining accesses to information that should no longer be proposed and lead to protection breaches
Missing information repositories-obsolescence management	Not considering the information management system applications maintenance and survey could lead to the loss of access to crucial information. The IM plan should include the management of the nominal repositories' lifecycle, back-up solutions as well as a disaster recovery plan.
Inadequate back-up policy	Not ensuring that the information is backed up periodically in a back-up solution having the required retention durability and remains retrievable could lead to late discovery of information loss. The back-up policy should plan regular checks to ensure that information is not corrupted over time.

Good Practices

Some good practices gathered from the references are provided in Table 4:

Table 4. Information Management Good Practices. (SEBoK Original)

Good Practice Name	Good Practice Description
Guidance	• Refer to the applicable Data Management guide or standard or norm applicable to your domain or industrial context. • When applicable, the DAMA Guide to the Data Management Body of Knowledge provides an excellent, detailed overview of IM at both the project and enterprise level.
Information as an Asset	Recognize that information is a strategic asset for the organization and needs to be managed and protected.
Information Storage Capacity	Plan for the information storage capacity that is foreseen in your context, without forgetting to anticipate the increase of information volume based on the regular survey of the amount of information to be managed.
Effective Information Access	Ensure that the users are aware of the presence of the information and the relevant people access the information they need to know. Information that is not accessible or not used loses value that should come from the usage of the information.

Data Modeling	• Invest time and effort in designing data models that are consistent with the underlying structures and information needs of the organizations involved. • Cross-organization data modeling should focus on semantics (the exact meaning of terms or data items). Agreement on formats or table structures is insufficient: Terms often mean different things to different organizations. • Model for interoperability: Assume the data will be used in integrating with new, different systems later on. This requires a focus on identifiers, metadata, and provenance; and structures that can scale across organizational boundaries.
Quality Management	The cost impact of using poor quality information can be enormous. Be rigorous about managing the quality of information, including considering carefully the validation and release steps in the information lifecycle.
Information Repository Design	• The impact of managing information poorly can also be enormous (e.g., violating intellectual property or export control rules). • Make sure that the IM requirements are captured and implemented in the information repository, and that all users of the repository are aware of the rules that they need to follow and the penalties for infringement.
Uncontrolled modification prevention	Organize the information management life cycle and security to prevent from undesirable and/or untraced modification of the information.

Quality Management

- Lead Authors:
- Quong Wang, Massood Towhidnejad, and David Olwell
- Contributing Authors:
- Dick Fairley and Garry Roedler

-

Whether a systems engineer delivers a product, a service, or an enterprise, the deliverable should meet the needs of the customer and be fit for use. Such a deliverable is said to be of high quality. The process to assure high quality is called quality management.

Overview

Over the past 80 years, a *quality movement* has emerged to enable organizations to produce high quality deliverables. This movement has gone through four stages:

1. **Acceptance Sampling** was developed to apply statistical tests to assist in the decision of whether or not to accept a lot of material based on a random sample of its content.
2. **Statistical Process Control** (SPC) was developed to determine if production processes were stable. Instead of necessarily measuring products, processes are measured instead. Processes that departed from a state of statistical control were far more likely to develop low quality deliverables.
3. **Design for Quality** focused on designing processes that were robust against causes of variation, reducing the likelihood that a process would go out of control, and accordingly reducing the monitoring requirements.
4. **Six sigma** methods are applied the tools and power of statistical thinking to improve other aspects of the organization.

Definitions

The American Society for Quality [1] provides the following definitions:

- Acceptance Sampling involves the inspection of a sample to decide whether to accept the entire lot. There are two types of sampling:
  - In attributes sampling, the presence or absence of a characteristic is noted in each of the units inspected.
  - In variables sampling, the numerical magnitude of a characteristic is measured and recorded for each inspected unit. This involves reference to a continuous scale of some kind.
- SPC is the application of statistical techniques to control a process. It is often used interchangeably with the term “statistical quality control.”
- Quality is a subjective term for which each person or sector has its own definition. In technical usage, quality can have two meanings:
  - The characteristics of a product or service that bear on its ability to satisfy stated or implied needs.
  - A product or service free of deficiencies. According to Joseph Juran, quality means “fitness for use.” According to Philip Crosby, it means "conformance to requirements."
- Six Sigma is a method that provides organizations with tools to improve the capability of their business processes. This increase in performance and decrease in process variation leads to defect reduction and improvement in profits, employee morale, and quality of products or services. Six Sigma quality is a term generally used to indicate a process is well controlled (±6 s from the centerline in a control chart).

Quality Attributes

Quality attributes, also known as quality factors, quality characteristics, or non-functional requirements, are a set of system functional and non-functional requirements that are used to evaluate the system performance. There are a large number of system quality attributes identified in the literature (e.g. MSDN 2010, Barbacci et al. 1995). Depending on the type of the system being considered, some of these attributes are more prominent than others. Ideally, a system would be optimized for all the quality attributes that are important to the stakeholders, but this is an impossible task. Therefore, it is important to conduct a trade-off analysis to identify the relationship between the attributes and establish whether a change in one attribute would positively or negatively affect any other attributes. An example of such trade-off is shown in Table 1 below. (See SEBoK discussion on specialty engineering for additional information on quality attributes.)

Table 1. Attribute Trade Off. (SEBoK Original)

	Flexibility	Maintainability	Reliability
Flexibility		+	-
Maintainability	+		+
Reliability	-	+	

Finding the right set of quality attributes is the first step in quality control and management. In order to achieve high quality, quality must be measured, monitored, managed, and improved on. Therefore, in order to increase the overall system quality, it is necessary to:

- identify and prioritize the quality attributes
- identify the metrics that can be used for these attributes
- measure and monitor the attributes
- validate the measurements
- analyze the result of those measurements
- establish processes and procedures that result in improved system quality, based on the analysis.

Quality Attributes for Products

Quality attributes for a product focus on the conformance to the specifications for the product; frequently these are manufacturing specifications. Examples include physical characteristics (length, weight, finish, capacity, etc.) being inside a given tolerance range. The physical characteristics can be related to the function of the product or to aesthetic qualities.

A single product may have a vector of quality attributes of high dimension as well as an associated region in which the vector is expected to be. Often the quality is summarized by saying the item is "in compliance" (if the vector is in the acceptable region) or "defective" (if the vector is outside the acceptable region).

Quality Attributes for Services

Quality of services plays a major role in customer satisfaction, which is the measurement of the overall system quality. Services can be divided into two major categories: primary and secondary. The city public transportation system, the U.S. postal service, or the medical services provided by a hospital are all examples of primary services. Services that provide help to a customer are secondary services, which are typically referred to as a *customer service*. Identifying the appropriate quality attributes is critical in the quality management of services. Some examples of service quality attributes include: affordability, availability, dependability, efficiency, predictability, reliability, responsiveness, safety, security, usability, etc. Again, depending on the type of the service, some of these attributes are more prominent than the others.

For example, in the case of services that are provided by the hospital, one may potentially be more interested in the availability, reliability, and responsiveness than the security (typically hospitals are assumed to be safe) and the affordability (typically insurance covers the majority of the cost). Of course, if the patient does not have a good insurance coverage, then the importance of affordability will increase (de Knoning, 2006).

Quality Attributes for Enterprises

An enterprise typically refers to a large, complex set of interconnected entities that includes people, technologies, processes, financial, and physical elements. Clearly, a typical enterprise has a number of internal and external stakeholders, and as a result there are a large number of quality attributes that will define its quality. Identifying the right set of attributes is typically more challenging in such a complex system. An example of an enterprise is the air traffic management system that is mainly responsible for the safe and efficient operation of the civil aviation within a country or collection of countries. There are many stakeholders that are concerned about the overall quality of the system, some example of these stakeholders and some of the primary quality attributes that they are concerned with are identified in Table 2.

Table 2. Enterprise Stakeholders and their Quality Attributes. (SEBoK Original)

Stakeholders	Primary Quality Attributes
Passengers	Safety, affordability, and reliability
Airlines	Adaptability, efficiency, and profitability
Air Traffic Controller	Safety, reliability, and usability
Hardware & Software Developers	Reliability, fault tolerance, and maintainability
Government/Regulatory Agency	Safety, reliability, affordability, etc.

Measuring Quality Attributes

Quality cannot be achieved if it cannot be measured. The Measurement System Analysis (MSA) (Wheeler and Lynday 1989) is a set of measuring instruments that provide an adequate capability for a team to conduct appropriate measurements in order to monitor and control quality. The MSA is a collection of:

- **Tools** - measuring instruments, calibration, etc.
- **Processes** - testing and measuring methods, set of specifications, etc.
- **Procedures** - policies and procedures and methodologies that are defined by the company and/or regulatory agency
- **People** - personnel (managers, testers, analysis, etc.) who are involved in the measurement activities
- **Environment** - both environmental setting and physical setting that best simulate the operational environment and/or the best setting to get the most accurate measurements

Once the quality attributes are identified and prioritized, then the MSA supports the monitor and control of overall system quality.

Additional details about measurement are presented in the measurement article.

Quality Management Strategies

Acceptance Sampling

In acceptance sampling many examples of a product are presented for delivery. The consumer samples from the lot and each member of the sample is then categorized as either *acceptable* or *unacceptable* based on an attribute (attribute sampling) or measured against one or more metrics (variable sampling). Based on the measurements, an inference is made as to whether the lot meets the customer requirements.

There are four possible outcomes of the sampling of a lot, as shown in Table 3.

Table 3. Truth Table - Outcomes of Acceptance Sampling. (SEBoK Original)

	Lot Meets Requirement	**Lot Fails Requirement**
Sample Passes Test	No error	Consumer risk
Sample Fails Test	Producer risk	No error

A sample acceptance plan balances the risk of error between the producer and consumer. Detailed ANSI/ISO/ASQ standards describe how this allocation is performed (ANSI/ISO/ASQ A3534-2-1993: *Statistics—Vocabulary and Symbols—Statistical Quality Control*).

Statistical Process Control

SPC is a method that was invented by Walter A. Shewhart (1931) that adopts statistical thinking to monitor and control the behaviors and performances of a process. It involves using statistical analysis techniques as tools in appropriate ways, such as providing an estimate of the variation in the performance of a process, investigating the causes of this variation, and offering the engineer the means to recognize when the process is not performing as it should based on the data. (Mary et al. 2006, 441). In this context, *performance* is measured by how well the process is performed.

The theory of quality management emphasizes managing processes by fact and maintaining systematic improvement. All product developments are a series of interconnected processes that have variation in their results. Understanding variation with SPC technology can help the process executors understand the facts of their processes and find the improvement opportunities from a systematic view.

Control charts are common tools in SPC. The control chart is also called the Shewhart 3-sigma chart. It consists of 3 limit lines: the center line, which is the mean of statistical samples, and the upper and lower control limit lines, which are calculated using the mean and standard deviation of statistical samples. The observed data points or their statistical values are drawn in the chart with time or other sequence orders. Upper and lower control limits indicate the thresholds at which the process output will be considered as *unlikely*. There are two sources of process variation. One is common cause variation, which is due to inherent interaction among process components. Another is assignable cause, which is due to events that are not part of the normal process. SPC stresses bringing a process into a state of statistical control, where only common cause variation exists, and keeping it in control. A control chart is used to distinguish between variation in a process resulting from common causes and assignable causes.

If the process is in control, and if standard assumptions are met, points will demonstrate a normal distribution around the control limit. Any points outside either of the limits, or in systematic patterns, imply a new source of variation would be introduced. A new variation means increased quality cost. Additional types of control charts exist, including: cumulative sum charts that detect small, persistent step change model departures and moving average charts, which use different possible weighting schemes to detect persistent changes (Hawkins and Olwell 1996).

Design for Quality

Variation in the inputs to a process usually results in variation in the outputs. Processes can be designed, however, to be robust against variation in the inputs. Response surface experimental design and analysis is the statistical technique that is used to assist in determining the sensitivity of the process to variations in the input. Such an approach was pioneered by Taguchi.

Six Sigma

Six sigma methodology (Pyzdek and Keller, 2009) is a set of tools to improve the quality of business processes; in particular, to improve performance and reduce variation. Six sigma methods were pioneered by Motorola and came into wide acceptance after they were championed by General Electric.

Problems resulting in variation are addressed by six sigma projects, which follow a five-stage process:

1. **Define** the problem, the stakeholders, and the goals.
2. **Measure** key aspects and collect relevant data.
3. **Analyze** the data to determine cause-effect relationships.
4. **Improve** the current process or **design** a new process.
5. **Control** the future state or **verify** the design.

These steps are known as **DMAIC** for existing processes and **DMADV** for new processes. A variant of six sigma is called lean six sigma wherein the emphasis is on improving or maintaining quality while driving out waste.

Standards

Primary standards for quality management are maintained by ISO, principally the IS0 9000 series [2]. The ISO standards provide requirements for the quality management systems of a wide range of enterprises, without specifying how the standards are to be met. The key requirement is that the system must be audited. ISO standards have world-wide acceptance.

In the United States, the Malcolm Baldridge National Quality Award presents up to three awards in six categories: manufacturing, service company, small business, education, health care, and nonprofit. The Baldridge Criteria [3] have become de facto standards for assessing the quality performance of organizations.

-

Measurement and the accompanying analysis are fundamental elements of systems engineering (SE) and technical management. SE measurement provides information relating to the products developed, services provided, and processes implemented to support effective management of the processes and to objectively evaluate product or service quality. Measurement supports realistic planning, provides insight into actual performance, and facilitates assessment of suitable actions (Roedler and Jones 2005, 1-65; Frenz et al. 2010).

Appropriate measures and indicators are essential inputs to tradeoff analyses to balance cost, schedule, and technical objectives. Periodic analysis of the relationships between measurement results and review of the requirements and attributes of the system provides insights that help to identify issues early, when they can be resolved with less impact. Historical data, together with project or organizational context information, forms the basis for the predictive models and methods that should be used.

Fundamental Concepts

The discussion of measurement in this article is based on some fundamental concepts. Roedler et al. (2005, 1-65) states three key SE measurement concepts that are paraphrased here:

1. **SE measurement is a consistent but flexible process** tailored to the unique information needs and characteristics of a particular project or organization and revised as information needs change.
2. **Decision makers must understand what is being measured.** Key decision-makers must be able to connect *what is being measured* to *what they need to know* and *what decisions they need to make* as part of a closed-loop, feedback control process (Frenz et al. 2010).
3. **Measurement must be used to be effective.** Measurement of the Quality attribute of the technical objectives along with the cost and schedule provides the overall effectiveness of the project.

Measurement Process Overview

The measurement process as presented here consists of four activities from Practical Software and Systems Measurement (PSM 2025) and described in (ISO/IEC/IEEE 15939; McGarry et al. 2002):

1. Establish and sustain commitment
2. Plan measurement
3. Perform measurement
4. Evaluate measurement

This approach has been the basis for establishing a common process across the software and systems engineering communities. This measurement approach has been adopted by the Capability Maturity Model Integration (CMMI) measurement and analysis process area (SEI 2010), as well as by international systems and software engineering standards (ISO/IEC/IEEE 15939; ISO/IEC/IEEE 15288; ISO/IEC/IEEE 12207; SAE 2018). The International Council on Systems Engineering (INCOSE) Measurement Working Group has also adopted this measurement approach for several of their measurement assets, such as the INCOSE SE Measurement Primer (Frenz et al. 2010) and Technical Measurement Guide (Roedler and Jones 2005). This approach has provided a consistent treatment of measurement that allows the engineering community to communicate more effectively about measurement. The

process is illustrated in Figure 1 from Roedler and Jones (2005) and McGarry et al. (2002).

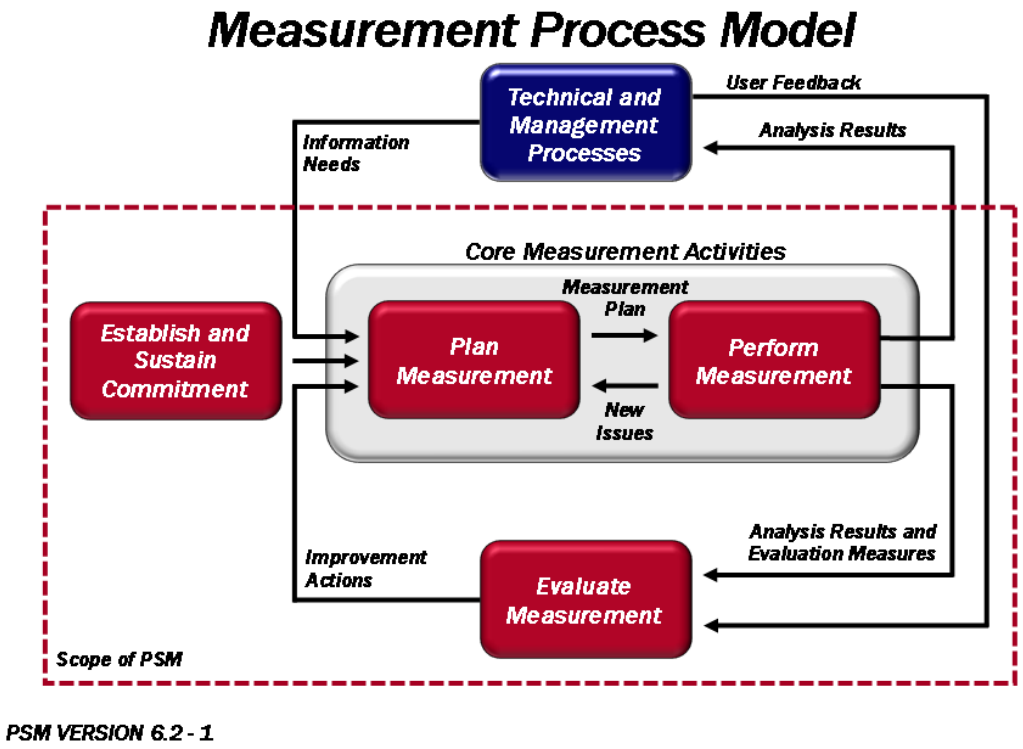

Figure 1. Four Key Measurement Process Activities (PSM 2025). Reprinted with permission of Practical Software and Systems Measurement (PSM [1]). All other rights are reserved by the copyright owner.

Establish and Sustain Commitment

This activity focuses on establishing the resources, training, and tools to implement a measurement process and ensure that there is a management commitment to use the information that is produced. Refer to PSM (2025) and SPC (2011) for additional detail.

Plan Measurement

This activity focuses on defining measures that provide insight into project or organization information needs. This includes identifying what the decision-makers need to know and when they need to know it, relaying these information needs to those entities in a manner that can be measured, and identifying, prioritizing, selecting, and specifying measures based on project and organization processes (Jones 2003, 15-19). This activity also identifies the reporting format, forums, and target audience for the information provided by the measures.

Here are a few widely used approaches to identify the information needs and derive associated measures, where each can be focused on identifying measures that are needed for SE management:

- The PSM approach, which uses a set of information categories, measurable concepts, and prosepctive measures to aid the user in determining relevant information needs and the characteristics of those needs on which to focus (PSM 2025).
- The (GQM) approach, which identifies explicit measurement goals. Each goal is decomposed into several questions that help in the selection of measures that address the question and provide insight into the goal achievement (Park, Goethert, and Florac 1996).

- ISO/IEC/IEEE 15939:2017, clause 6.3.2 provides specific information on planning for measurement. In clause 6.3.2.4, it covers the identification of information needs and the selection and definition of measures (ISO/IEC/IEEE 15939).

The following are good sources for candidate measures that address information needs and measurable concepts/questions:

- PSM Web Site - Sample Measurement Specifications (PSM 2025)
- Table: Information Categories - Measurable Concepts - Prospective Measures (ICM Table) (PSM 2025)
- PSM Guide, Version 4.0, Chapters 3 and 5 (PSM 2000)
- SE Leading Indicators Guide, Version 2.0, Section 3 (Roedler et al. 2010)
- Technical Measurement Guide, Version 1.0, Section 10 (Roedler and Jones 2005, 1-65)
- Safety Measurement (PSM White Paper), Version 3.0, Section 3.4 (Murdoch 2006, 60)
- Security Measurement (PSM White Paper), Version 3.0, Section 7 (Murdoch 2006, 67)
- Measuring Systems Interoperability, Section 5 and Appendix C (Kasunic and Anderson 2004)
- Measurement for Process Improvement (PSM Technical Report), version 1.0, Appendix E (Statz 2005)
- New Opportunities for Architecture Measurement (Carson and Kohl 2012)
- System Development Performance Measurement (NDIA and PSM 2011)
- Continuous Iterative Development (CID) Measurement Specifications (PSM 2025)
- Digital Engineering Measurement Framework, Version 1.1 (DE Measurement Framework 2022)

The INCOSE *SE Measurement Primer* (Frenz et al. 2010) provides a list of attributes of a good measure with definitions for each attribute; these attributes include *relevance, completeness, timeliness, simplicity, cost effectiveness, repeatability, and accuracy.* Evaluating candidate measures against these attributes can help assure the selection of more effective measures.

The details of each measure need to be unambiguously defined and documented. Templates for the specification of measures and indicators are available on the PSM website (2025) and in Goethert and Siviy (2004).

Perform Measurement

This activity focuses on the collection and preparation of measurement data, measurement analysis, and the presentation of the results to inform decision makers. The preparation of the measurement data includes verification, normalization, and aggregation of the data, as applicable. Analysis includes estimation, feasibility analysis of plans, and performance analysis of actual data against plans.

The quality of the measurement results is dependent on the collection and preparation of valid, accurate, and unbiased data. Data verification, validation, preparation, and analysis techniques are discussed in PSM (2025) and SEI (2010). Per TL 9000, Measurements Handbook, *The analysis step should integrate quantitative measurement results and other qualitative project information, in order to provide managers the feedback needed for effective decision making* (QuEST Forum 2020). This provides richer information that gives the users the broader picture and puts the information in the appropriate context.

There is a significant body of guidance available on good ways to present quantitative information. Edward Tufte has several books focused on the visualization of information, including *The Visual Display of Quantitative Information* (Tufte 2001).

Other resources that contain further information pertaining to understanding and using measurement results include

- PSM (2025)
- ISO/IEC/IEEE 15939:2017, clauses 6.3.3.3 and 6.3.4
- Roedler and Jones (2005), sections 6.4, 7.2, and 7.3
- INCOSE Systems Engineering Handbook, 5th Edition, Section 2.3.4.7 (INCOSE 2023)
- SE Leading Indicators Guide, Version 2.0, Sections 3 & 4 (Roedler et al. 2010)

- System Development Performance Measurement (NDIA and PSM 2011)
- Continuous Iterative Development (CID) Measurement Specifications (PSM 2025)
- Digital Engineering Measurement Framework, Version 1.1 (DE Measurement Framework. 2022)

Evaluate Measurement

This activity involves the analysis of information that explains the periodic evaluation and improvement of the measurement process and specific measures. One objective is to ensure that the measures continue to align with the business goals and information needs, as well as provide useful insight. This activity should also evaluate the SE measurement activities, resources, and infrastructure to make sure it supports the needs of the project and organization. Refer to PSM (2025) and *Practical Software Measurement: Objective Information for Decision Makers* (McGarry et al. 2002) for additional detail.

Systems Engineering Leading Indicators

Leading indicators are aimed at providing predictive insight that pertains to an information need. A SE leading indicator is *a measure for evaluating the effectiveness of a how a specific activity is applied on a project in a manner that provides information about impacts that are likely to affect the system performance objectives* (Roedler et al. 2010). Leading indicators may be individual measures or collections of measures and associated analysis that provide future systems engineering performance insight throughout the life cycle of the system; they *support the effective management of systems engineering by providing visibility into expected project performance and potential future states* (Roedler et al. 2010).

As shown in Figure 2, a leading indicator is composed of characteristics, a condition, and a predicted behavior. The characteristics and conditions are analyzed on a periodic or as-needed basis to predict behavior within a given confidence level and within an accepted time range into the future. More information is also provided by Roedler et al. (2010).

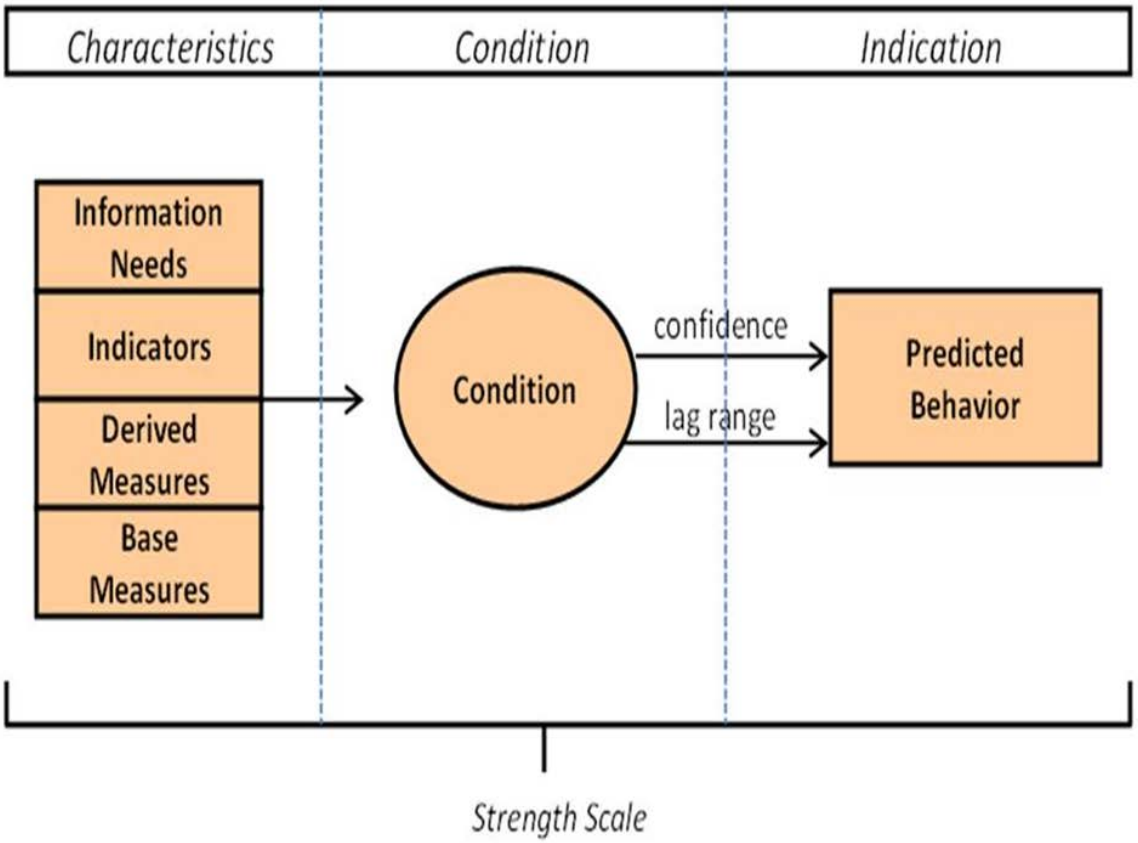

Figure 2. Composition of a Leading Indicator (Roedler et al. 2010). Reprinted with permission of the International Council on Systems Engineering (INCOSE [2]) and Practical Software and Systems Measurement (PSM [1]). All other rights are reserved by the copyright owner.

Technical Measurement

Technical measurement is the set of measurement activities used to provide information about progress in the definition and development of the technical solution, ongoing assessment of the associated risks and issues, and the likelihood of meeting the critical objectives of the acquirer. This insight helps an engineer make better decisions throughout the life cycle of a system and increase the probability of delivering a technical solution that meets both the specified requirements and the mission needs. The insight is also used in trade-off decisions when performance is not within the thresholds or goals.

Technical measurement includes measures of effectiveness (MOEs), measures of performance (MOPs), and technical performance measures (TPMs) (Roedler and Jones 2005, 1-65). The relationships between these types of technical measures are shown in Figure 3 and explained in the reference for Figure 3. Using the measurement process described above, technical measurement can be planned early in the life cycle and then performed throughout the life cycle with increasing levels of fidelity as the technical solution is developed, facilitating predictive insight and preventive or corrective actions. More information about technical measurement can be found in the *NASA Systems Engineering Handbook*, *System Analysis, Design, Development: Concepts, Principles, and Practices*, and the *Systems Engineering Leading Indicators Guide* (NASA December 2007, 1-360, Section 6.7.2.2; Wasson 2006, Chapter 34; Roedler et al. 2010).

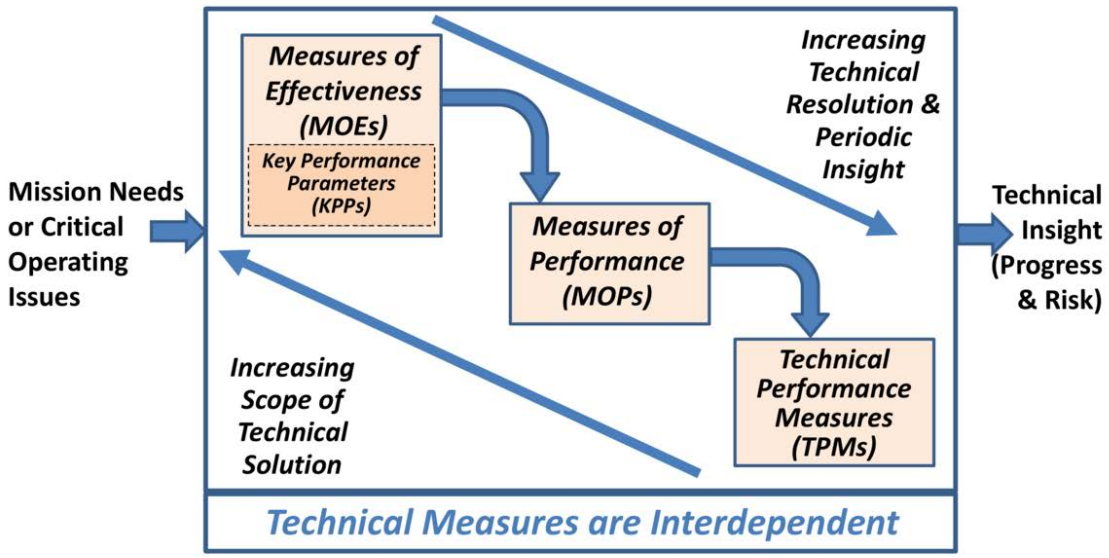

Figure 3. Relationship of the Technical Measures (Roedler et al 2010). Reprinted with permission of the International Council on Systems Engineering (INCOSE [1]) and Practical Software and Systems Measurement (PSM [1]). All other rights are reserved by the copyright owner.

Service Measurement

The same measurement activities can be applied for service measurement; however, the context and measures will be different. Service providers have a need to balance efficiency and effectiveness, which may be opposing objectives. Good service measures are outcome-based, focus on elements important to the customer (e.g., service availability, reliability, performance, etc.), and provide timely, forward-looking information.

For services, the terms critical success factors (CSF) and key performance indicators (KPI) are used often when discussing measurement. CSFs are the key elements of the service or service infrastructure that are most important to achieve the business objectives. KPIs are specific values or characteristics measured to assess achievement of those objectives.

More information about service measurement can be found in the *Service Design* and *Continual Service Improvement* volumes of BMP (2010, 1). More information on service SE can be found in the Service Systems Engineering article.

Linkages to Other Systems Engineering Management Topics

SE measurement has linkages to other SEM topics. The following are a few key linkages adapted from Roedler and Jones (2005):

- Project Planning – SE measurement provides the historical data and supports the estimation for, and feasibility analysis of, the plans for realistic planning.
- Project Assessment and Control – SE measurement provides the objective information needed to perform the assessment and determination of appropriate control actions. The use of leading indicators allows for early assessment and control actions that identify risks and/or provide insight to allow early treatment of risks to minimize potential impacts.
- Risk Management – SE risk management identifies the information needs that can impact project and organizational performance. SE measurement data helps to quantify risks and subsequently provides information about whether risks have been successfully treated to a level that that they can be managed or eliminated. Risk management relies heavily on measurement, as it quantifies potential impacts and provides data to support informed decision-making, resource allocation, and the evaluation of risk treatments or handling strategies. Thus, the risks and risk treatments identify potential new measures to provide this insight. Additionally, the results of measures may also help to identify potential new risks that should be considered for assessment and handling.
- Decision Management – SE Measurement results inform decision making by providing objective insight.

Digital Engineering (DE) Measurement

As stated in the article “Digital Engineering Measures: Research and Guidance” by McDermott et al. in the March 2022 issue of INCOSE Insight magazine, “Digital Engineering (DE) and model-based approaches are two components of enterprise digital transformation that have great promise to improve the efficiency and productivity of engineering activities, particularly for complex engineered systems.” The trends towards Digital Engineering (DE) have continued, so the industry needs to be able to define and perform measurement to manage DE and make informed decisions. For DE, “data and models are the core products undergoing measurement.” (McDermott et al. 2022).

In June 2022, a coalition consisting of INCOSE, NDIA, AIA, SERC, and the US DoD R&E joined with PSM to develop and publish the PSM Digital Engineering Measurement Framework. This framework is intended to supplement the foundational measurement guidance provided by ISO/IEC/IEEE 15939, PSM 2025. And other resources listed in this article. This framework provides “the initial set of constructs … to isolate those measurements that are most closely linked to the primary benefits of DE.” The guidance focuses on supplemental measures for DE specific information needs that are intended to be used along with relevant measures for other information needs of the project and other engineering activities. The DE measures “focus on the digital information products (data and models) developed and used across a product life cycle.” (DE Framework 2022). This framework can be obtained from the PSM website (www.psmsc.com) or from the collaborating organizations. Version 2 of the framework is expected to be published in December 2025.

The DE measurement framework considers measures needed to provide insight for the scope of DE work activities. These include:

- Digital Infrastructure (Environment and Supporting Tools)
- Life Cycle Models (Phases/Stages and Decision Points)
- Process Models (Work Processes, Digital Artifacts)
- Data and Model Ontology (System)
- Operational, System, and Discipline Specific Data and Models

Continuous Iterative Development (CID)

Since most systems have great quantities of software, it would be remiss to ignore recent developments in measurement for software development employing Continuous Iterative Development (CID) approaches (often referred to as agile). Similarly to the DE Measurement Framework, this work is meant to supplement the foundational measurement guidance provided by ISO/IEC/IEEE 15939, PSM 2021 and other resources listed in this article. The CID Measurement Framework was developed and published by a team spanning Practical Software and Systems Measurement (PSM), the National Defense Industrial Association (NDIA), and the International Council on System Engineering (INCOSE). The framework details “common information needs and measures that are effective for evaluating CID approaches. The information needs address the team, product, and enterprise perspectives to provide insight and drive decision-making. The framework also identifies and specifies an initial set of measures identified as practical measures to address these information needs.” (CID Framework 2021) It also includes a series of diagrams and an ontology to describe the development approaches and terminology used. (PSM 2025) The guidance is provided in three volumes that cover basic guidance, prioritized information needs for CID projects, and ten specifications for prospective measures. All of the volumes can be obtained from the PSM website (www.psmsc.com) or from the collaborating organizations.

Practical Considerations

Key pitfalls and good practices related to SE measurement are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing SE Measurement are provided in Table 1.

Table 1. Measurement Pitfalls. (SEBoK Original)

Name	Description
Golden Measures	• Looking for the one measure or small set of measures that applies to all projects. • No one-size-fits-all measure or measurement set exists. • Each project has unique information needs (e.g., objectives, risks, and issues). • The one exception is that, in some cases with consistent product lines, processes, and information needs, a small core set of measures may be defined for use across an organization.
Single-Pass Perspective	• Viewing measurement as a single-pass activity. • To be effective, measurement needs to be performed continuously, including the periodic identification and prioritization of information needs and associated measures.
Unknown Information Need	• Performing measurement activities without the understanding of why the measures are needed and what information they provide. • This can lead to wasted effort. Avoid "measurement for measurement sake".
Inappropriate Usage	• Using measurement inappropriately, such as measuring the performance of individuals or making interpretations without context information. • This can lead to bias in the results or incorrect interpretations.

Good Practices

Some good practices gathered from the references are provided in Table 2.

Table 2. Measurement Good Practices. (SEBoK Original)

Name	Description
Periodic Review	• Regularly review each measure collected.
Action Driven	• Measurement by itself does not control or improve process performance. • Measurement results should be provided to decision makers for appropriate action.
Integration into Project Processes	• SE Measurement should be integrated into the project as part of the ongoing project business rhythm. • Data should be collected as processes are performed, not recreated as an afterthought.
Timely Information	• Information should be obtained early enough to allow necessary action to control or treat risks, adjust tactics and strategies, etc. • When such actions are not successful, measurement results need to help decision-makers determine contingency actions or correct problems.
Relevance to Decision Makers	• Successful measurement requires the communication of meaningful information to the decision-makers. • Results should be presented in the decision-makers' preferred format. • Allows accurate and expeditious interpretation of the results.
Data Availability	• Decisions can rarely wait for a complete or perfect set of data, so measurement information often needs to be derived from analysis of the best available data, complemented by real-time events and qualitative insight (including experience).
Historical Data	• Use historical data as the basis of plans, measure what is planned versus what is achieved, archive actual achieved results, and use archived data as a historical basis for the next planning effort.
Information Model	• The information model defined in ISO/IEC/IEEE (2007) provides a means to link the entities that are measured to the associated measures and the identified information need, and also describes how the measures are converted into indicators that provide insight to decision-makers.

Additional information can be found in the *Systems Engineering Measurement Primer*, Section 4.2 (Frenz et al. 2010), and INCOSE *Systems Engineering Handbook*, Section 5.7.1.5 (2012).

Knowledge Area: System Concept Definition

System Concept Definition

Contents of this Knowledge Area

- Business or Mission Analysis (Tami Katz) (Lou Wheatcraft and Mike Ryan)
- Stakeholder Needs Definition (Tami Katz) (Lou Wheatcraft and Mike Ryan)
- Lead Author:
- Tami Katz
- Contributing Authors:
- Lou Wheatcraft, Mike Ryan, Garry Roedler, and Rick Adcock
-

Concept Definition is the set of systems engineering (SE) activities in which the problem space as well as the needs and requirements of the business (or enterprise) and stakeholders are closely examined. Concept definition begins before any formal definition of the system-of-interest (SoI) is developed.

The Concept Definition activities include Business or Mission Analysis and Stakeholder Needs Definition. Within these two activities the enterprise or project decision makers, as well as additional key stakeholders, describe *what* a solution should accomplish and *why* it is needed. Both *why* and *what* need to be answered before consideration is given to *how* the problem will be addressed (i.e., what type of solution will be implemented) and *how* the solution will be defined and developed.

Concept Definition Activities

There are two primary activities discussed under Concept Definition: Business or Mission Analysis and the definition of Stakeholder Needs:

1. The Business or Mission Analysis activity defines the problem, threat, or opportunity being addressed which could result in a new or modified product or service. This process also includes identification of major stakeholders, the mission, goals, and objectives of the SoI, the measures of success, identification of business needs and requirements, and identification of the SoI life cycle concepts.
2. The Stakeholder Needs Definition activity uses the inputs from the Business or Mission Analysis effort to identify an integrated set of needs based on inputs from the major stakeholders, higher-level requirements, and an analysis of the life cycle concepts, drivers, constraints, and risks.

The products and artifacts produced during Concept Definition are then used in the System Definition process.

Drivers of Concept Definition

There are many considerations associated with concept definition activities, which are further elaborated below.

The Role of Architecture Development

The activities of Business or Mission Analysis and Stakeholder Needs Definition occur concurrently with the processes of System Architecture Design Definition. The activities to address a full set of needs includes identification of SoI life cycle concepts, external interfaces and constraints, as well as candidate solutions and an exploration of the architecture (logical and functional).

Drivers of Solution on Problem Definition

During Concept Definition, the problem definition and solution exploration depend on each other: solutions should be developed to respond appropriately to well-defined problems; and problem definitions should be constrained by what is feasible in the solution space. System analysis is used to provide the links between problems and solutions.

There are two paradigms that drive the ways in which concept definition is done: push and pull. The pull paradigm is based on providing a solution to an identified problem or gap, such as a missing mission capability for defense or infrastructure. The push paradigm is based on creating a solution to address a perceived opportunity, such as the emergence of an anticipated product or service that is attractive to some portion of the population (i.e. whether a current market exists or not). This can impact other life cycle processes, such as verification and validation, or alpha/beta testing as done in some commercial domains.

As systems generally integrate existing and new system elements in a mixture of push and pull, it is often best to combine a bottom-up approach with a top-down approach to take into account legacy elements, as well as to identify the services and capabilities that must be provided in order to define applicable interface requirements and constraints. This is discussed in Applying Life Cycle Processes.

New System or Modification of Existing System

The activities of concept definition determine whether the enterprise strategic goals and business needs will be addressed by a new system, a change to an existing system, a service, an operational change, or some other solution.

For a new system, the organization or customer has decided to start with a “blank piece of paper”. This is often referred to as a green-field system, and analysis efforts during concept definition characterize the as-is or present-state of the SoI in terms of the problem, threat, or opportunity and then characterize the to-be or future-state of the SoI in obtaining the resolution of the problem, threat, or opportunity.

An existing system can be evolved or transformed into the desired system. This is often referred to as a brown-field system, and the data that has been established for the original system can be used as inputs into the analysis efforts during concept definition activities. The existing system may have been developed for other purposes, the stakeholder needs or the operational environment may have changed, e.g., a change in threats. The analysis effort will explore the problem space and possible solutions to the gaps of the existing system to address the problem, threat or opportunity.

Business or Mission Analysis

- Lead Author:
- Tami Katz
- Contributing Authors:
- Lou Wheatcraft and Mike Ryan

-

The primary start to the engineering of any system-of-interest (SoI) is to obtain an understanding the objectives behind the development of the SoI, which is performed as part of the Concept Definition process.

Business or Mission Analysis, the first process performed in Concept Definition, establishes a definition of the overall strategic problem or opportunity and identification of potential solution classes to address the problem (or take advantage of an opportunity) (ISO/IEC/IEEE 15288). The solution could be a new system, a change to an existing system, a service, an operational change or some other solution.

This analysis effort identifies the primary purpose(s) of the SoI (its "mission"). The second Concept Definition process is called Stakeholder Needs Definition, which explores what capabilities are needed to accomplish the mission or the intended use of the system.

Business or Mission Analysis is often performed iteratively with the Stakeholder Needs Definition process to better understand the problem space, as well as options in the solution space.

Purpose and Definition

The purpose of Business or Mission Analysis is to understand a mission or market problem, threat, or opportunity, and to establish the goals, objectives and measures of success of a potential solution class. This consists of a strategic analysis related to emerging needs, capability gaps, threats, opportunities, and potential solutions by a project team or by an organization to obtain its business objectives prior to establishing a project team.

Principles and Concepts

For the SoI under development, success depends on the project team's understanding the data and information that constitutes the purpose of the SoI (*why?*), acceptability or desirability of a solution (*what?*), measures (*how well?*), and the conditions in which the SOI must operate (*in what operating environment?*)

Prior to SoI development, a project champion works with key stakeholders to clearly define the problem, threat, or opportunity for which the project team is to address. Identifying the specific problem, threat, or opportunity will enable the project team to understand if the project is worth doing, why the system is needed, and the expected capabilities of the SoI. The next step is to identify the mission, goals, and objectives (MGOs) based on the defined problem, threat or opportunity, as well as the measures of success.

- The *Mission* statement is based on the analysis of a problem, threat, or opportunity that the project was formed to address, the expected outcome of the SoI being developed, and defines the “why”. Why does the project exist? Why is the SoI needed? What value does it bring to the organization?
- *Goals* are elaborated from the mission statement to communicate what must be achieved to result in a successful mission. Goals allow the organization to divide the mission statement into manageable pieces and promote a shared understanding between the project team and the business operations level stakeholders of what needs to be done to achieve the mission.
- *Objectives* are elaborated from the goals to provide more details concerning what must be done that will result in the goals and mission to be achieved. What does the project team need to do to achieve the goals? What does the SoI need to do to achieve the goals?

- *Measures* are quantitative metrics used to validate the SoI against the objectives as well as to manage system development across the life cycle, expressed as Measures of Effectiveness (MOE) (reference Measurement).

As part of the Business or Mission Analysis effort, an initial assessment by key stakeholders of the SoI life cycle concepts is used to support identification of candidate solution classes. The organization then performs an evaluation of whether to proceed with development of the SoI based on analysis of the data and alignment with the organization's enterprise strategy. Upon agreement to proceed, the data from the Business and Mission Analysis effort is used by the project team to complete the rest of the concept development process for the SoI, as shown in Figure 1.

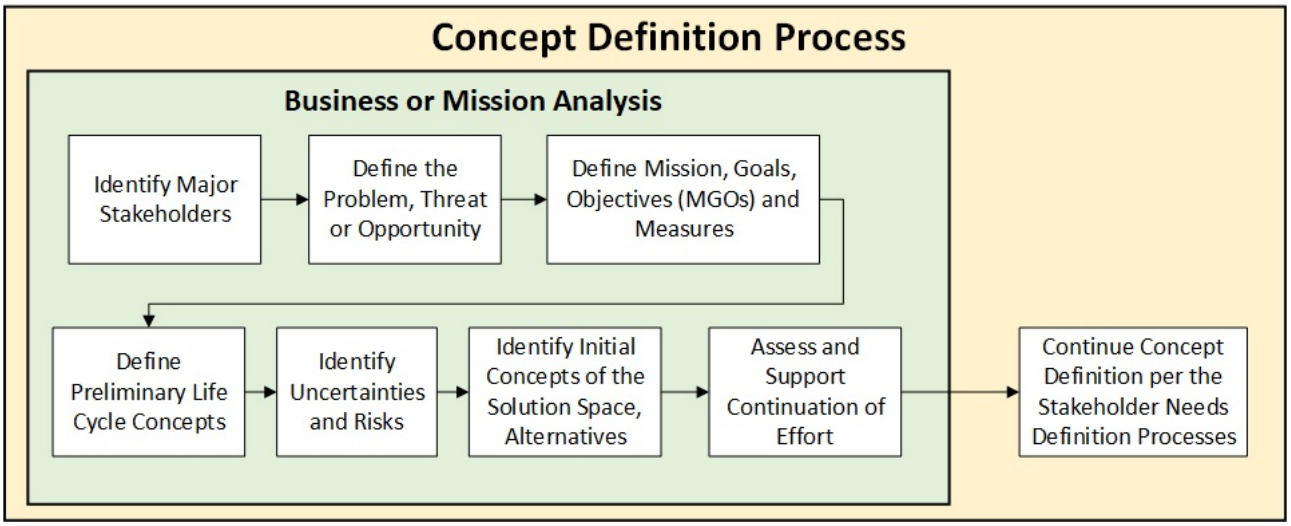

Figure 1. Business or Mission Analysis addresses the effort to generate project success, which is provided to the project team for further concept definition activities. (SEBoK Original)

There are several outputs of the Business or Mission Analysis process:

- identification of major stakeholders,
- definition of the problem, threat, or opportunity to which the project must address,
- elaboration of the MGOs and measures of success,
- identification of preliminary life cycle concepts and the preferred solution classes,
- traceability of strategic problems, threats, opportunities, MGOs, and measures of success to the preferred solution classes, and
- confirmation of organizational support.

The effort of Business or Mission Analysis is often done at a business enterprise level, where the initial assessment results in the authorization for a project and associated budget along with an acquisition concept. For the project team responsible for developing the SoI, this means seeking an understanding of this content to ensure the outcomes of the project align with the organization's overall strategy and rationale for developing that particular SoI.

The output from the Business or Mission Analysis is then provided to the project team for use in additional analysis that establishes an overall set of needs for the solution (described in Stakeholder Needs Definition).

Process Approach

Identify Major Stakeholders

During this process the initial stakeholder identification is performed. This can be captured in a stakeholder register, noting each stakeholder and their involvement with the SoI and project, as well as establishment a ranking of the stakeholders. This list is expanded upon during Stakeholder Needs Definition. At this phase, the stakeholders will often include key members from the organization at the enterprise level.

Define the Problem, Threat, or Opportunity

Identifying the specific problem, threat or opportunity will enable the project team to understand why the system is needed, and which capabilities, functions, performance, and features that are important to the customers, users, operators, maintainers, and disposers of the system.

There are four steps to defining the problem, threat, or opportunity:

1. Identification of the organization's strategic and business operations level stakeholders that are impacted by the problem or threat or those who will benefit by pursuing the opportunity.
2. Collaboration with these stakeholders to understand how they are impacted by the problem or threat, or by those that will benefit by pursuing the opportunity.
3. Clear definition of the problem, threat, or opportunity.
4. Stakeholder concurrence with the problem, threat, or opportunity statement.

Example Problem/Threat/Opportunity statement: Marketing is seeing an increase of work from home personnel that are purchasing more coffee makers. Existing coffee makers have single functions while consumers want a multi-function hot beverage maker to produce a blend of options like traditional brew or espresso. There is a huge opportunity if first to market. (INCOSE GtNR 2022)

Define the Mission, Goals, Objectives and Measures

To achieve the MGOs and measures, the project champion collaborates with the stakeholders that participated in defining the problem, threat, or opportunity to better understand what they view as an acceptable outcome by asking them a series of questions:

- How do they define success?
- What measures would the stakeholders use to determine success?
- What is the intended use of the SoI and in what operating environment?
- What capabilities, features, functions, and performance do they need?
- What are their expectations for quality and compliance (such as with standards and regulations)?
- What specific outcome(s) do they expect once the SoI is delivered?
- What are the measures of success, e.g., measures of effectiveness (MOE), expected of the SoI?

For cases where there is no existing SoI, a common approach is to characterize the "as is" or "present state" in terms of the problem, threat, or opportunity and then characterize the "to be" or "future state" in terms of the resolution of the problem, neutralizing the threat, or the ability to pursue the opportunity.

For existing systems that need to be updated, a common approach is to list the problems or issues with the existing "as-is" system and the reasons it needs to be changed. Key information includes what value they believe will result from the change by addressing: What can the existing SoI no longer do, what performance needs to be improved, what changes need to be made concerning interactions with external systems, what updates are needed as a result of changes to applicable standards and regulations, what updates are needed as a result of changes in the operational environment or new threats (e.g., security)?

It is also important to understand different perspectives. The problem, threat, or opportunity, MGOs, and measures from a business perspective may be different than the user's perspective, both must be addressed. The user does not necessarily care about the developing organization's profits, time to market, market share, etc., they care about how the resulting SoI meets their needs. Thus, there could be several sets of MGOs and measures that need to be defined and met by the project team from both a business perspective and a user perspective of the SoI to be developed. This may lead to conflicts, e.g., product price vs. profitability vs. market share, which need to be prioritized based on the organizational enterprise strategy.

Examples (derived from INCOSE GtNR 2022):

- Mission statement: Increase revenue by providing a home-based, one-stop, multi-function hot beverage maker.
- Consumer Goals: Product a blend of options. Obtain home brew beverage quickly.
- Consumer Objective: Options of brew or expresso. Receive finished home brew coffee within minutes upon request.
- Consumer-focused Measure: Finished home brew provided within 2 minutes of activation at the selected temperature. Rationale: Consumer survey results.
- Business Goals: Increase revenue. Increase market share.
- Business Objective: Increase market share of Company X sales regions.
- Business-focused Measure: Improve current market share of Company X sales regions by 20%. Rationale: Aligns with the enterprise strategic vision.

Capture Preliminary Life Cycle Concepts

Life cycle concepts, such as the operational concept, define what the SoI needs to do and how well during its intended use in the expected operational environment, from multiple perspectives. This includes various use cases with expected interactions with external systems, identification of drivers and constraints, expected risks to success in the context of the MGOs and measures.

Preliminary life cycle concepts are defined by the organization and include preliminary concepts for acquisition, development, manufacturing or coding, verification, validation, deployment, operations, support, and retirement. Operational concepts include high level operational modes or states, operational scenarios, potential use cases, misuse cases, loss scenarios, or usage within a proposed business strategy. These concepts enable feasibility analysis and evaluation of solution options. For example, concerning acquisition and development how much of the development effort will be done inhouse or outsourced to a supplier? Who will be the overall integrator? If development is done in house, what are the concepts for the supply chain for parts and components?

In a Model-Based Systems Engineering effort, these life cycle concepts are generated using mission analysis, such as defining use cases associated with users and life cycle stage (Figure 2). Reference Model-Based Systems Engineering (MBSE) for more information regarding usage of MBSE.

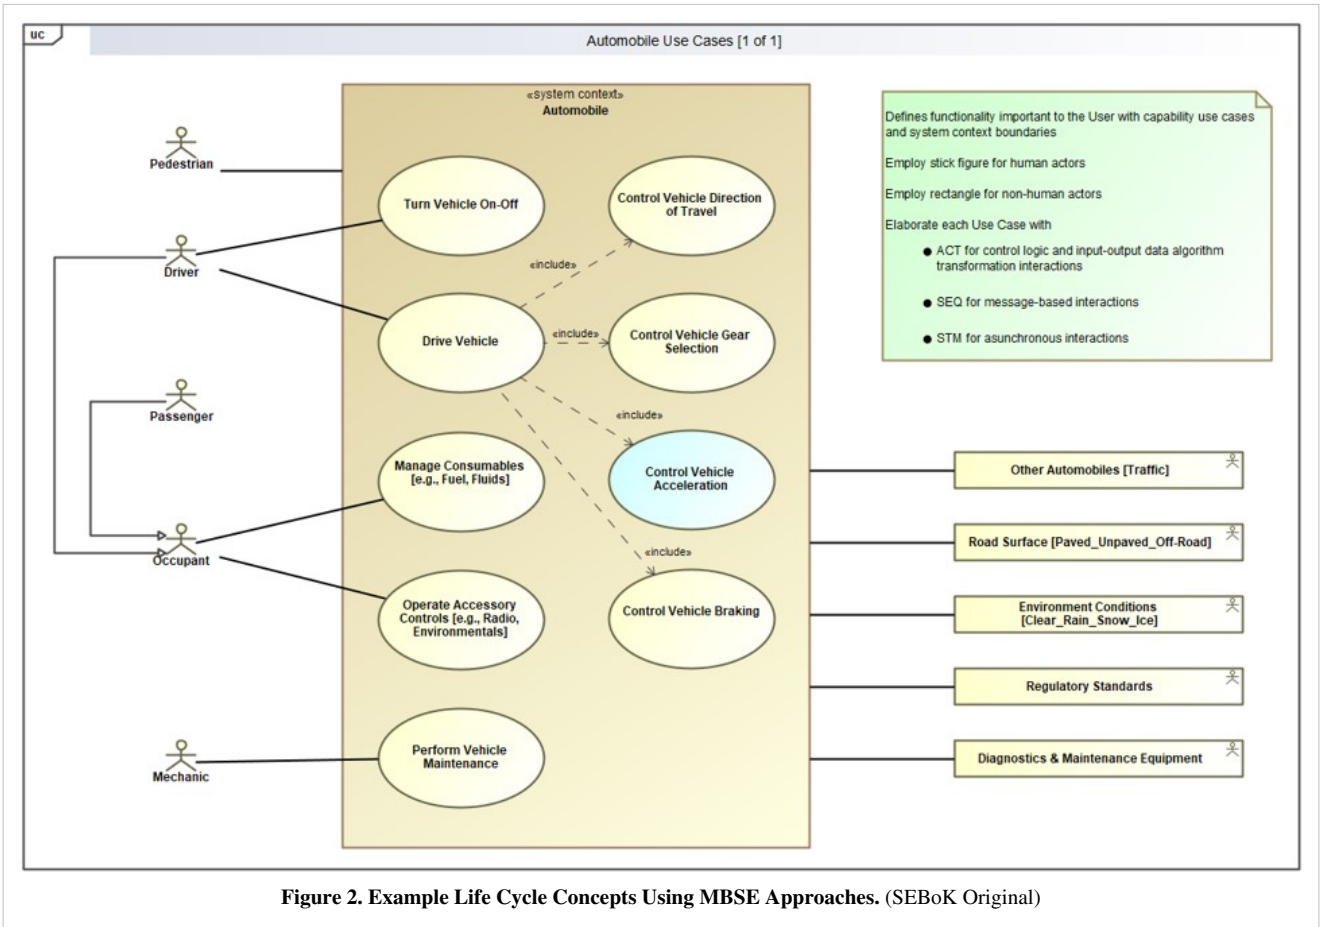

Figure 2. Example Life Cycle Concepts Using MBSE Approaches. (SEBoK Original)

The life cycle concepts will be further refined within the stakeholder needs definition process. As part of the preliminary life cycle concepts, candidate solution classes are suggested for a possible range of approaches to address the MGOs, as part of a Functional Architecture definition activity.

Identify Uncertainties and Risks

The preliminary life cycle concepts include some level of uncertainty. This leads to risks which need to be identified and managed using the Risk Management process. These risks may also serve as inputs to the generation of additional life cycle concepts (such as addressing cyber security or hazards to successful operation).

Identify Preliminary Concepts of the Solution Space, Including Alternatives

A solution class refers to the means of achieving a solution. Examples include development of a new system, modifying or upgrading an existing system, leveraging multiple existing systems, or generating operational changes.

Possible solution classes to address the problem, threat, or opportunity are assessed against the preliminary life cycle concepts, MGOs and measures. Feasibility of a solution class and its capability to meet the strategic needs are key decision criteria, as well as feasibility considerations in terms of cost, schedule, technology, legal, ethical, environmental, sustainability, etc. The Decision Management process is used to evaluate alternatives and to guide selection. The assessment of alternatives can include modeling, simulation, analytical techniques, or expert judgment to understand the risks, feasibility, and value of the alternative solution classes.

The conclusion of this effort results in the identification of preliminary concepts of the solution space, including alternatives, which are traceable to the organization defined problems/threats/opportunities and MGOs/measures.

Assessment of Continuation of Effort

Upon the conclusion of the Business or Mission Analysis process the organization performs an evaluation on whether to commence with development of the SoI. The key determination is alignment with the enterprise strategy. If the effort is to be continued, a project team will take the outcomes of the Business or Mission Analysis effort and commence with the Stakeholder Needs Definition activity.

Stakeholder Needs Definition

- Lead Author:
- Tami Katz
- Contributing Authors:
- Lou Wheatcraft and Mike Ryan

-

Stakeholder Needs Definition, the second process in Concept Definition, explores what capabilities are needed by various stakeholders for the system-of-interest (SoI) to accomplish the mission. The outcome of the Stakeholder Needs Definition process is used as the basis of System Validation, as well as input into the System Requirements Definition process.

Note that the first process, Business or Mission Analysis, is often performed iteratively with Stakeholder Needs Definition to better understand the problem, threat, or opportunity space, as well as options of the solution space.

Purpose and Definition

Stakeholder needs represent a user, acquirer, customer, and other stakeholders perspective of the SoI, which are then transformed into system requirements which communicate a developer perspective of the SoI. When stakeholder needs are combined with results of multiple analysis activities that includes risks, drivers, constraints, and life cycle concepts analysis, as shown in Figure 1, the result is an overall integrated set of needs.

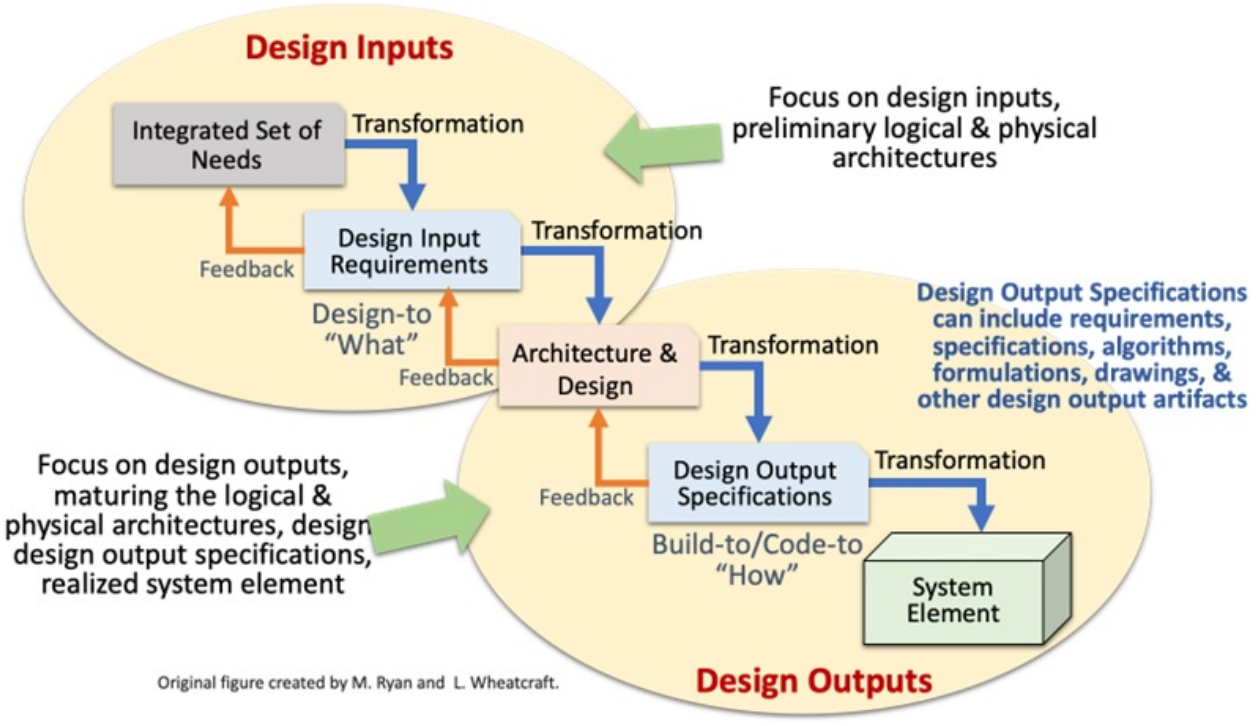

Figure 1. Establishment of an Integrated Set of Needs ensures that all perspectives are analyzed during the Stakeholder Need Definition process, including risks, drivers, constraints, and life cycle concepts analysis and maturation. This figure is reprinted with permission of Lou Wheatcraft and Mike Ryan. All other rights are reserved by the copyright owner.

The establishment of the integrated set of needs forms the basis of a full understanding of the capabilities expected of the SoI, and these needs are ultimately transformed into a set of design-input requirements on the SoI as part of the System Requirements Definition process.

Principles and Concepts

The results of the Business or Mission Analysis is provided as inputs into the Stakeholder Needs Definition process (shown in Figure 2). This input includes the problem, threat or opportunity statement capturing why the project is worth doing, the mission, goals and objectives (MGOs) and measures of success used as the criteria for assessing project success, along with identification of major stakeholders, initial life cycle concepts, and initial concepts of the solution space (architecture and design).

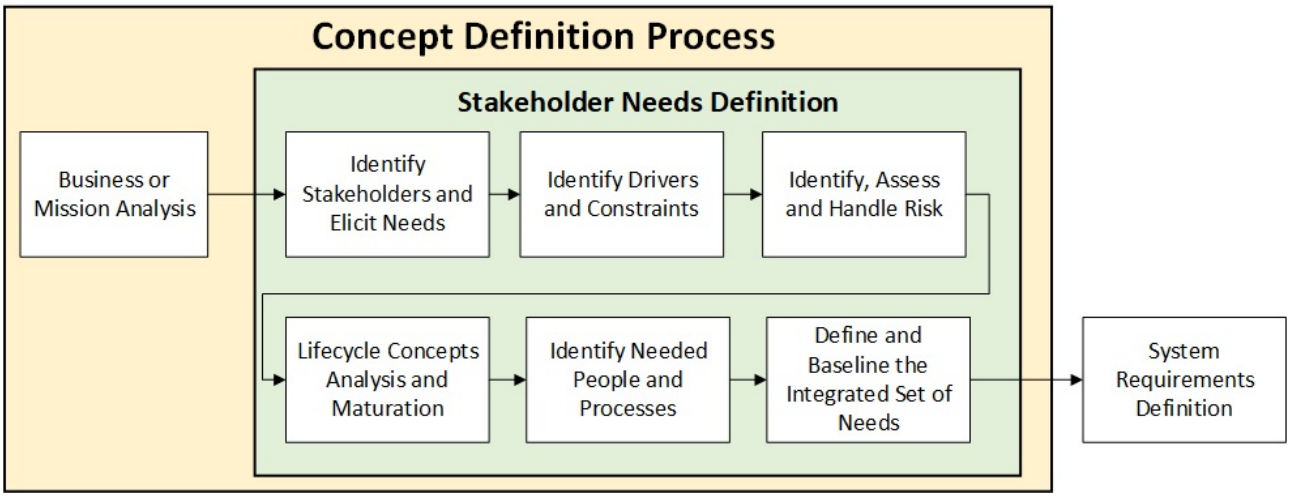

Figure 2. Stakeholder Needs Definition expands upon the Business or Mission Analysis results to refine the set of needs for the System of Interest. (SEBoK Original)

The Stakeholder Needs Definition process continues the life cycle concepts definition activities to ensure the system-of-interest (SoI) provides the capabilities needed by users and other stakeholders in the intended operational environment. This process is much more than identification and elicitation of need or requirement statements from various stakeholders, it consists of a series of analysis activities done to ensure that all parameters are captured, including risks, drivers, constraints, as well as the SoI life cycle concepts analysis and maturation; this effort results in an integrated set of needs as shown in Figure 3.

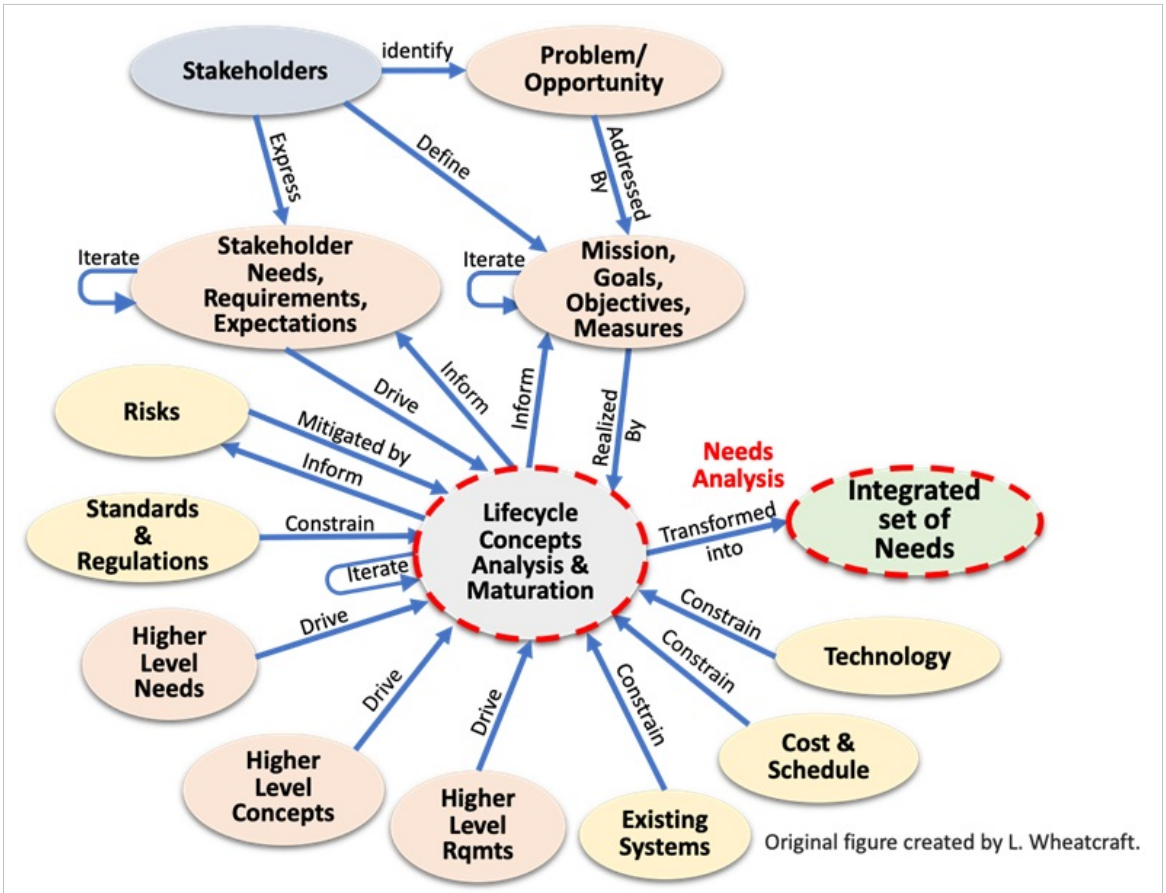

Figure 3. Establishment of an integrated set of needs ensures that all perspectives are analyzed during the Stakeholder Need Definition process, including risks, drivers, constraints, and life cycle concepts analysis and maturation. This figure is reprinted with permission of Lou Wheatcraft. All other rights are reserved by the copyright owner.

The result of this process is a well-formed integrated set of needs that is correct, consistent, complete, and feasible. It is this set of needs that defines the scope of the project which the organization agrees to provide the resources necessary for developing the SoI, and against which the requirements, design, and the realized SoI will be validated against.

Nomenclature discussion

This process is frequently referred to as the "Stakeholder Needs and Requirements" process. Because various guides, textbooks, and standards refer to stakeholder “expectations, needs, and requirements” as if they are the same, resulting in confusion as to what is an “expectation” versus a “need” and a “requirement”, this article focuses on the process of developing an integrated set of stakeholder needs. The term "stakeholder requirements" is considered a set of requirements on the SoI established by the stakeholder, as transformed from their needs, which are provided as additional input towards the life cycle concepts analysis and maturation activities from which the integrated set of needs is defined. In Figure 3, this is designated as both "stakeholder needs, requirements, and expectations" as well as the "higher-level requirements" inputs.

Process Approach

Inputs to the Stakeholder Needs Definition Process

The inputs from the Business or Mission Analysis process includes identification of major stakeholders, definition of the problem, threat, or opportunity, elaboration of the MGOs and measures of success, capture of preliminary life cycle concepts, and identification of initial concepts of the solution space (architecture and design).

Activities of the Process

There are several activities performed during this process:

- Identify additional stakeholders or classes of stakeholders across the life cycle.
- Elicit, capture, consolidate and prioritize stakeholder needs, requirements, and expectations.
- Identify drivers and constraints on the SoI and its development efforts.
- Identify potential risks (such as threats and hazards) that could prevent the SoI from successful operation (see Risk Management for further information on addressing risks).
- Mature and analyze the life cycle concepts.
- Identify, baseline, and manage the integrated set of needs.

The activities behind each of these are described in the following sections.

Identify Stakeholders

Stakeholders are the primary source of needs and requirements, therefore for the project to be successful, all relevant stakeholders must be identified and included from the beginning of the project. Leaving out a relevant stakeholder often results in missing needs and requirements and a failure to pass system validation. Stakeholders can include, but are not limited to, customers, sponsors, organization decision makers, regulatory organizations, developing organizations, integrators, testers, users, operators, maintainers, support organizations, the public at large (within the context of the business and proposed solution), and those involved in the disposal or retirement of the SoI. Stakeholders can be both internal and external to the organization. There can be many stakeholders for a SoI over its life cycle; therefore, considering the life cycle concepts provides a thorough source for stakeholder identification. Examples of stakeholders are provided in Table 1.

Table 1. Stakeholder Identification Based on Life Cycle Stages. (SEBoK Original)

Life Cycle Stage	Example of Related Stakeholders
Concept	Paying customer, sponsor, project team, project manager, procurement, research and development, suppliers, regulating authorities, public, marketing, end users, operators, compliance office, regulators, owners of enabling systems, owners of external systems, Approving Authorities
Development	Acquirer, subject matter experts (SMEs), system architects, design engineers, suppliers, procurement, suppliers (technical domains for components realization), integration team
Production, Integration, Verification and Validation	Production organization, process engineers, quality control, production verification, product acceptance, supply chain, test engineers, system integration engineers, system verification engineers, system validation engineers, operators/users, owners of enabling systems, facility personnel, contracting, approving authorities, regulators, safety personnel, security personnel
Logistics and Maintenance	Customer/technical support, replacement part providers, service technicians, trainers, IT, quality engineer, inspectors, those conducting post development system verification and system validation activities
Operation	Normal users, unexpected users, etc.
Disposal	Operators, waste management, regulators, public

A key part of stakeholder identification is to determine who the approving authorities are within the group of stakeholders. It cannot be assumed that the only stakeholder that has this authority is the "customer". The approving authorities include stakeholders that are responsible for formally certifying, qualifying, and approving the system for use in its operational environment by its intended users. There can be approving authorities both within and external to the organization, especially for highly-regulated systems.

An approach for recording the list of stakeholders is to use a stakeholder register that includes key information for each stakeholder and how they are involved with the SoI. It is recommended that the project team re-evaluate the stakeholder community periodically to ensure successful engagement with stakeholders, keeping them engaged across all life cycle activities, and managing changes in stakeholders and their needs.

Stakeholder Needs Elicitation

For stakeholder needs elicitation, the project team engages the stakeholders to understand their needs, requirements, and expectations for all life cycle stages. The elicitation activities allow the project team to discover what is needed, what processes exist, how stakeholders interact with the SoI, what happens over the SoI's life cycle from their perspective (examples are provided below).

It is recommended that several techniques or methods be considered during elicitation activities to better accommodate the diverse set of sources (INCOSE NRM 2022):

- structured brainstorming workshops,
- interviews and questionnaires,
- workshops or focus groups,
- use of visual and descriptive content associated with the SoI,
- technical, operational, and/or strategy documentation review, and
- feedback from System Verification and System Validation processes.

A broad range of topics are discussed with the stakeholders:

- Obtain feedback on the outputs from the Business and Mission Analysis process (problem, threat, opportunity, MGOs, etc.).
- Identify the life cycle stages the stakeholder represents and their role.
- For each life cycle stage, obtain input on expected and off-nominal use cases, scenarios, misuse cases, and loss scenarios.
- Identify the desired capabilities and functions from their perspective.
- Identify interactions with external systems.
- Obtain input on their view of quality and other "ilities", such as reliability, testability, serviceability, etc.
- Inquire about their view of risks and hazards, along with likelihood and consequence.
- For each need, capture rationale concerning "why".
- Ask about criticality of the stated needs and relative priorities of all inputs obtained.

During elicitation activities, it is important to ask the stakeholders to provide rationale for and prioritize what they are asking for. Some needs will be especially important to the stakeholder, while others may be "nice-to-haves" and not critical to the system being able to accomplish its intended use. There will be some things that the stakeholder may be able to "live without" given budget or schedule constraints. Providing rationale often reveals the real need, especially when the stakeholder expresses a need as an implementation.

The information obtained from the elicitation activities needs to be recorded with trace to the stakeholder register. In a Model-Based Systems Engineering (MBSE) effort, the elicited needs can be included in the MBSE system model and traced to the stakeholders.

Identify Drivers and Constraints

Drivers and constraints are things outside of the project's control that constrain or drive the solution space. Drivers and Constraints can include design constraints (parts, materials, organizational design best practices, etc.), design standards, production constraints (existing technology, facilities, equipment, cost, throughput, etc.), human factors, (human/machine interface - HMI), regulations (law), operating environment (natural, induced), other environment (social, cultural), existing systems: (interactions, interfaces, dependencies), technology maturity, cost, schedule.

Concurrently with the stakeholder elicitation activities, drivers and constraints need to be identified and recorded within the SoI's integrated dataset.

Identify, Assess, and Handle Risk

Risks are anything that could prevent the delivery of a successful SoI (providing what is needed, within budget and schedule, with the needed quality), anything that could impact the intended use of the SoI in its intended environment by its intended users, or anything that would allow unintended users to prevent the intended use of the SoI or to use the SOI in an unintended manner, e.g., hack into an aircraft and use the aircraft as a weapon.

As part of the elicitation activities, issues and risks must be identified and assessed. The identified risks from the Business or Mission Analysis effort should be used as a starting point, and then additional elaboration of risks is needed along with how the project is expected to handle those risks. Stakeholders should be asked specifically about any issues and risk they think could prevent the SoI to be developed and delivered within budget, schedule, or risk during operations. Failing to address risk will result in an incomplete set of needs and resulting design input requirements resulting in a SoI that will fail system validation.

The project must do a risk assessment of each of the risks (see Risk Management). Some risks could lead to development of life cycle concepts as part of the mitigation (such as for hazards), which are expanded further in the next section.

Life Cycle Concepts Analysis and Maturation

As a result of life cycle concept analysis and maturation activities, architectural and analytical/behavioral models are developed. Based on the resulting information, the preliminary set of life cycle concepts established in Business or Mission Analysis are transformed into a mature set of life cycle concepts that are consistent, correct, complete, and feasible. Models and diagrams (such as those used in Model-Based Systems Engineering (MBSE) are excellent analysis tools for defining and maturing feasible life cycle concepts by providing a context for needs, and are key to help ensure correctness, completeness, and consistency of both individual needs and the integrated set of needs.

The logical architecture defines system boundary and functions, from which more detailed needs can be determined (interactions and interdependencies between logical elements of the system). As part of life cycle concept maturation, functions are defined, grouped logically, and relationships and interactions between those functions are captured. Supporting analytical and behavioral models can be developed to help assess behavior, interactions between parts of the architecture, and determine the performance characteristics of the functions.

Define and Baseline the Integrated Set of Needs

The project team derives an integrated set of needs that reflect the set of feasible system life cycle concepts, MGOs, measures, business operations level and system level stakeholder needs, drivers and constraints, and risk mitigation (Figure 4). These outcomes include results of the life cycle concepts analysis and maturation activity to determine expected functionality (what the stakeholders need the system to do), expected performance and quality ("how well" characteristics), the conditions of action, including triggering events, system states, and operating environments ("under what operating conditions"), as well as compliance with standards and regulations.

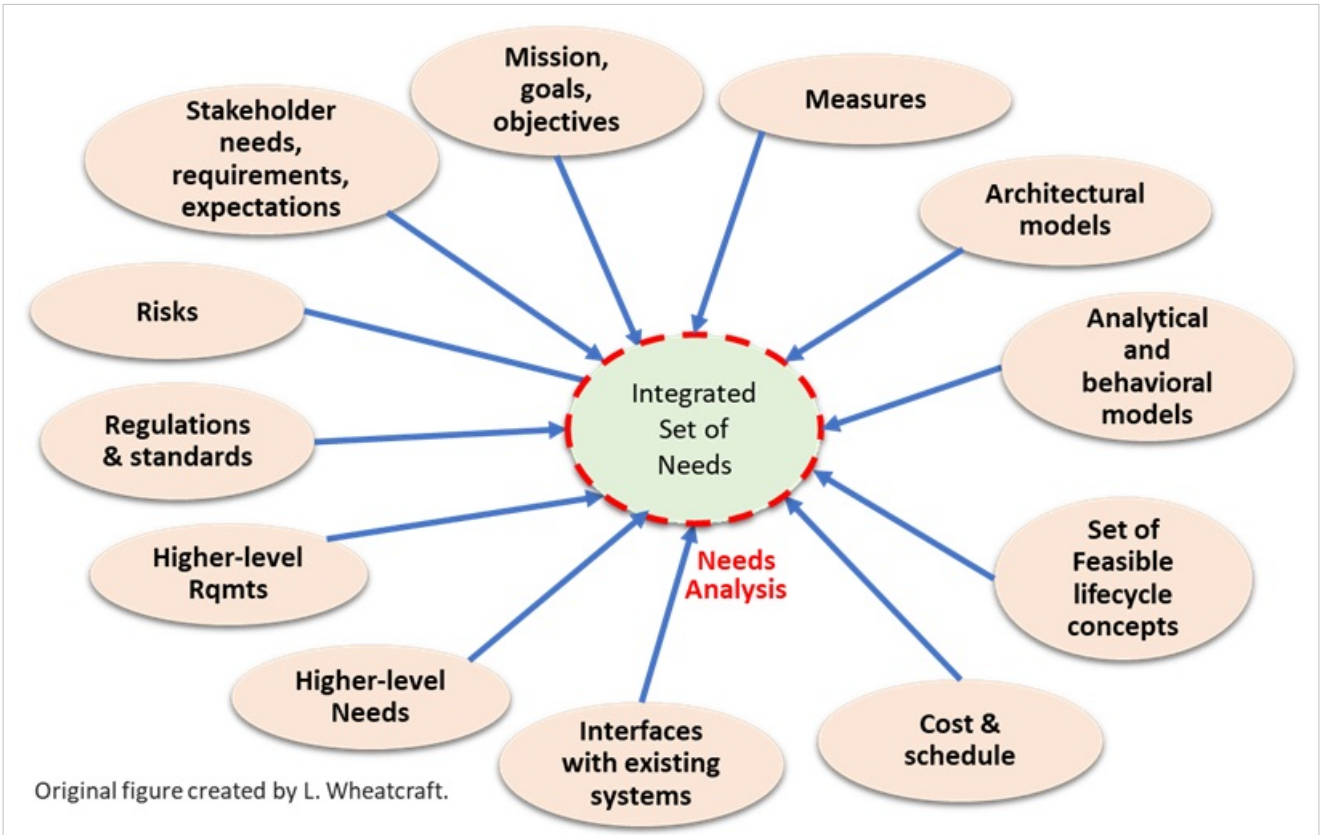

Figure 4. Input into the integrated set of needs. This figure is reprinted with permission of Lou Wheatcraft. All other rights are reserved by the copyright owner.

This integrated set of needs is what will be transformed into the set of design input requirements. In addition, it is this integrated set of needs which the design input requirements, design, and realized system will be validated against.

Needs are written in a structured, natural language from the perspective of what the stakeholders need the SoI to do. To help distinguish needs from the requirements, the needs statements do not include the word “shall” (or other word that depicts the statement is a requirement). It is recommended that need statements use a different format from requirements, such as: “The stakeholders need the system to” (INCOSE GtWR 2023). See Table 2 for example need statements.

Table 2. Example Need Statements. (SEBoK Original)

ID	Name	Need Statement	Rationale	Source
N1	Variable Temperature Settings.	The user needs the coffee maker to have two temperature settings (warm and hot) for the water temperature.	Focus groups provided input that a multi-select option for temperature is a desired feature.	Consumer input
N2	Prohibit Brew if Container Missing	The user needs the coffee maker to not brew unless a coffee container is in place.	Mitigation of risk of user error prior to starting coffee maker brew process.	Risk mitigation
N3	Coffee Maker Color Options	The company stakeholders need the coffee maker to come in four colors: black, grey, blue and red.	Marketing survey found that offering multiple colors provides competitive advantage with consumers.	Marketing stakeholder
N4	Ease of Use	The user needs the coffee maker to be easy to use (clearly defined user interface and a minimum of steps to get a cup of coffee).	Focus groups provided input that they are more likely to purchase products with simple user interfaces and operation controls.	Consumer input

The integrated set of needs must be recorded within the SoI's integrated dataset in a form and media suitable for review and feedback from the stakeholders, as well as a form that allows traceability. It is critical that the project team has confirmation from the stakeholders that their needs, requirements, expectations, MGOs, measures, drivers and constraints, and risk are properly communicated by integrated set of needs, this is supported by traceability. In a model-based systems engineering (MBSE) approach, the needs can be included in the system model, where they can be traced to their source (life cycle, stakeholder, MGO, risk, etc.).

Once the integrated set of needs is captured, they are used as inputs into the System Requirements Definition process.

System Requirements Definition

- Lead Author:
- Tami Katz
- Contributing Authors:
- Lou Wheatcraft and Mike Ryan

-

The System Requirements Definition process transforms the stakeholder view of desired capabilities into a technical, developer view of how the system can achieve those capabilities. System requirements describe requirements which the system-of-interest (SoI) must fulfill to satisfy the stakeholder needs and are expressed in an appropriate combination of well-formed textual statements and supporting models or diagrams. Inputs into this process are the life cycle concepts and integrated set of needs generated during the System Concept Definition activities.

System requirements play major roles in systems engineering, as they:

- Form the basis of system architecture and design activities.
- Form the basis of system integration and verification activities.
- Provide a means of communication between the various project team members that interact throughout the project.

Outputs of the System Requirements Definition process serve as inputs to a number of other technical processes, which include System Design Definition, System Architecture Definition, and System Verification.

Principles and Concepts

System Requirements Definition uses the outcome of the System Concept Definition activities to address what the system must do so that the integrated set of needs will be realized by the SoI. As shown in Figure 1, this information is then provided as input to the System Architecture Definition and System Design Definition processes, as well as the System Verification process.

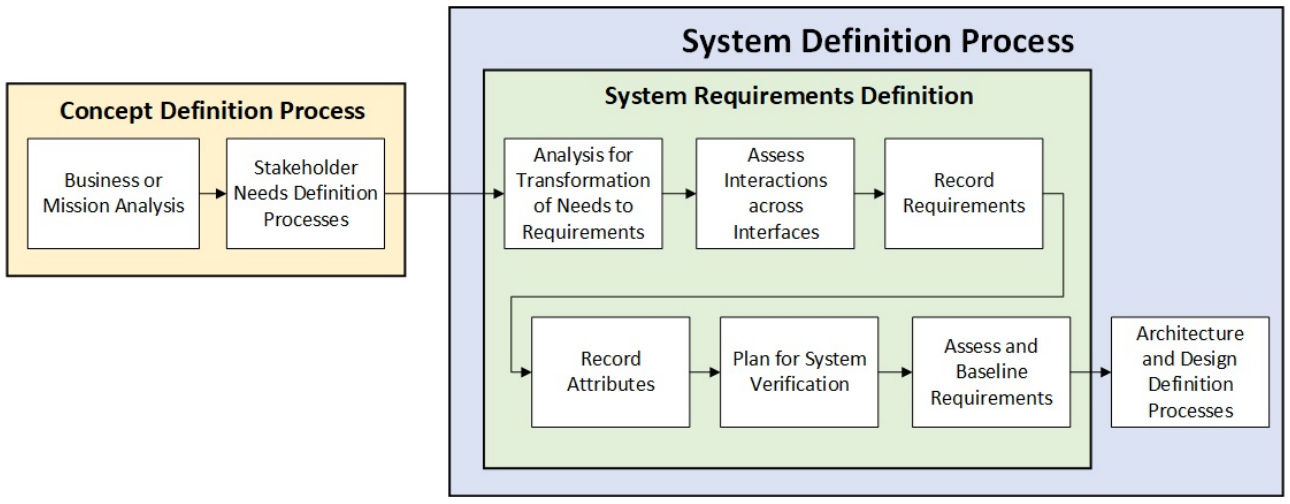

Figure 1. System Requirements Definition is the first activity in the System Definition Process. (SEBoK Original figure derived from ISO 15288-2023)

Defining requirements is not only an exercise in writing it is also an exercise in engineering. Every requirement represents an engineering decision as to what the SoI must do, or a quality the system must have, to meet the needs from which they were transformed. Determination of what the system must do to meet a need is through a process of detailed requirement analysis, which can include the development and use of models, simulations, and prototypes.

A requirement statement is the result of a "formal transformation of one or more needs or parent requirements into an agreed-to obligation for an entity to perform some function or possess some quality within specified constraints with acceptable risk." (INCOSE NRM 2022). In this context the use of the term “quality” means an inherent feature or a distinguishing attribute.

There are many types of requirements; this article describes the requirements which are used as inputs into the System Architecture and System Design Definition processes. As such, these requirements can be referred to as design input requirements, which are defined iteratively and recursively as the integrated system is decomposed into subsystems and system elements (the SoI could exist at any level of a system architecture).

Process for Generating System Requirements

Transforming Needs to System Requirements

The System Requirement Definition activities begin with the transformation of the integrated set of needs into a set of requirements for the SoI. These requirements must be appropriate to the level that the SoI exists within the system architecture and communicate “what” the SoI must do to meet the needs, avoiding requirements that state implementation of “how” to achieve the design realization of the physical SoI.

Needs communicate the stakeholder’s perspective concerning their expectations of what they need the system of interest (SoI) to do from an external, black box view.

- Example: The user needs the coffee maker to stop heating water once the user-selected temperature has been achieved.

The sources of needs are described in Stakeholder Needs Definition. These sources include the stakeholder expectations and needs, drivers and constraints, risk analysis, and life cycle concept analysis and maturation activities. These needs are treated as inputs to the System Requirement Definition process, which results in a set of design input requirements for the SoI.

Requirements communicate the technical, developer perspective concerning what the SoI must do to meet the stakeholder needs from an internal white box view.

- Example: The Coffee Maker shall stop the heating function once the selected Brew Temperature has been achieved.

The process of generating a requirement statement is more than changing the subject of the need statement, it is an analysis of what the system must do to achieve what is needed. There are many types of analyses and tools that are used to make this determination:

- functional analysis,
- interface analysis,
- data flow diagrams,
- performance analysis, and
- needs to transformation matrix.

Requirement analysis for functions and performance can be performed by using system models (supported by Model-Based Systems Engineering (MBSE) applications). Key enabling model views include activity diagrams, sequence diagrams, state machine diagrams, and structure diagrams (for hierarchy and interfaces). An example functional analysis is shown in Figure 2.

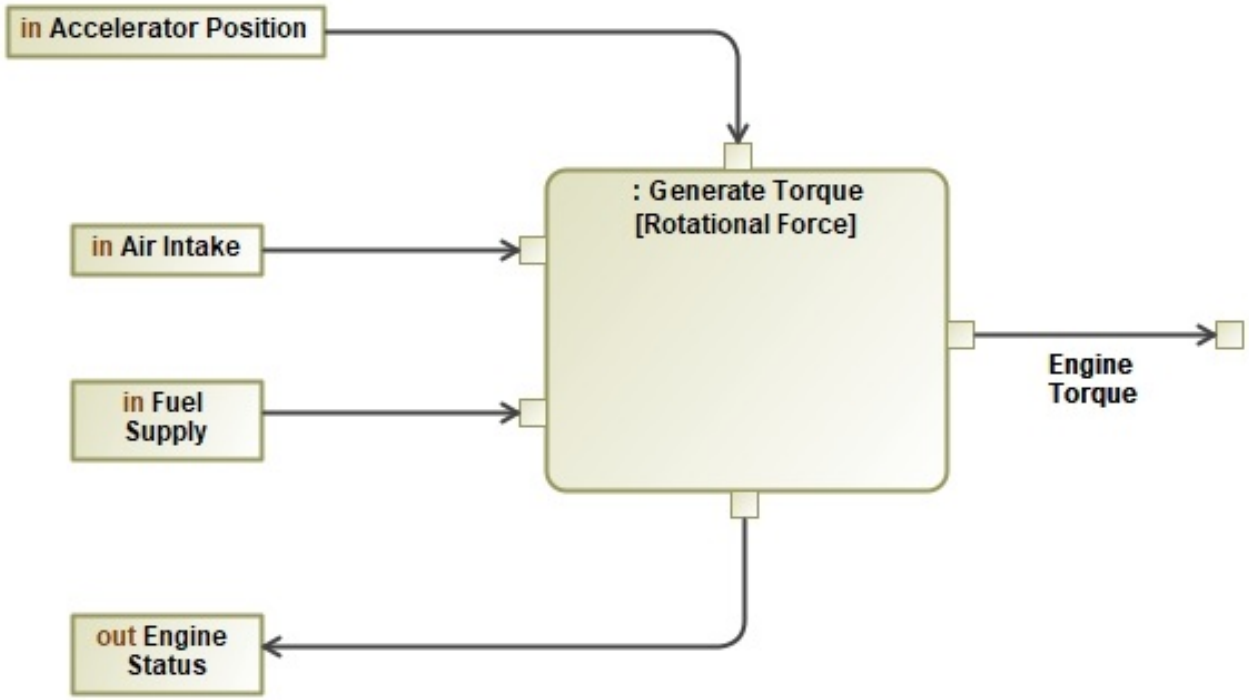

Figure 2. Example Function Analysis using a SysML Activity Diagram. (SEBoK Original)

Close and frequent coordination with the stakeholders is necessary to ensure the transformation is accurate and traceability is maintained. This results in a set of system requirements communicating measurable characteristics which can form the basis for system realization. A detailed analysis of a single need statement may result in multiple requirements expressing what the system must do to meet it, including definition of measurable performance criteria (INCOSE NRM 2022).

Use of Attributes

An attribute is additional information associated with an entity which is used to aid in its definition and management. Well-chosen attributes, when properly defined and tracked, can enable correct interpretation and management of requirements throughout the system life cycle. There are several useful attributes to consider:

- rationale,
- trace to source or parent,
- system verification success criteria,
- owner,
- category,
- status,
- criticality, and
- priority.

The use of the rationale attribute helps communicate why the requirement is needed, any assumptions made, the source of numbers, the results of related design studies, or any other related supporting information. This supports further requirements analysis and decomposition, as well as identifying the source of any requirement value. Defining the system verification success criteria helps ensure the requirement is well-formed, is verifiable, and aids in the planning for the project's verification program (INCOSE NRM 2022).

Categorizing Requirements

It is useful to organize the requirements into categories, grouping similar types of requirements together within a set. An example set of categories is shown in Table 1. While organizations may have different categorizations, for the set of requirements to be complete *each* category topic in Table 1 must be addressed.

Table 1. Example Types of Requirement Categories. (Derived from the INCOSE Needs and Requirements Manual)

Category	Description
Function/ Performance	The primary functions and associated performance that the SoI needs to perform in terms of its intended use. The functions address the capabilities and features the stakeholders expect the SoI to have; performance addresses how well, how many, how fast attributes of the function. Many of the primary functions involve interactions (interfaces) between the SOI and systems external to the SOI. All critical and high priority needs would be included in this category.
Fit/Operational	Requirements dealing with functions that deal with a secondary or enabling capabilities, functions, and interactions between the SoI and external systems needed for the system to accomplish its primary functions. This includes functions concerning the ability of the system to interface with, interact with, connect to, operate within, and become an integral part of the macro system it is a part. Fit includes human system interactions and interfaces as well as both the induced and natural environments (conditions of operations, transportation, storage, maintenance). For example, needs associated with safety, security, power, cooling, transportation and handling, storage, maintenance, and disposal.
Form	Physical Characteristics. The shape, size, dimensions, mass, weight, and other observable parameters and characterizes that uniquely distinguish a system. For software, form could address programming language, lines of code, memory requirements.
Quality	Fitness for use. For example, various "-ilities" such as reliability, testability, operability, availability, maintainability, operability, supportability, manufacturability, and interoperability.
Compliance	Conformance with design and construction standards and regulations.

See Table 2 for example requirement statements, attributes and categories.

Table 2. Example Requirement Statements. (SEBoK Original)

Reqt ID	Requirement Title	Requirement	Rationale	Category
R1	Variable Temperature Settings	The Coffee Maker shall have two user-selectable settings for coffee brewing: Warm: 96°C +/- 2°C, Hot: 100°C+/- 2°C.	Based on focus group inputs for selectable temperature; values are from analysis associated with consumer research surveys and safety regulations.	Function/Performance
R2	Prohibit Brew if Container Missing	If coffee container is not fully inserted into the brew location, the Coffee Maker shall prohibit brew function.	Protective measure related to off-nominal use case.	Function/Performance
R3	Operational Life	The Coffee Maker shall have an operational life greater than or equal to 3 years.	Analysis shows expected operational service of 1,000 hours over three years of usage, ensuring appliance lasts through the warranty period.	Quality
R4	User Inputs	The Coffee Maker shall limit the number of user inputs to: Power On, Brew Temperature, Brew Size, Brew Start.	User inputs are assessed from focus groups to minimum set of inputs to achieve coffee maker full set of life cycle concepts.	Fit/Operation

Requirements At Levels Within the Hierarchy

Requirements definition is an iterative and recursive process performed concurrently with the Architecture Definition Process. Upon determination of the system hierarchy, a requirement tree can be established showing the system level requirements and the supporting requirements at the lower-level elements of the hierarchy. Figure 3 shows an example flow from system requirement to lower-level requirements, and an example requirement tree is shown in Figure 4.

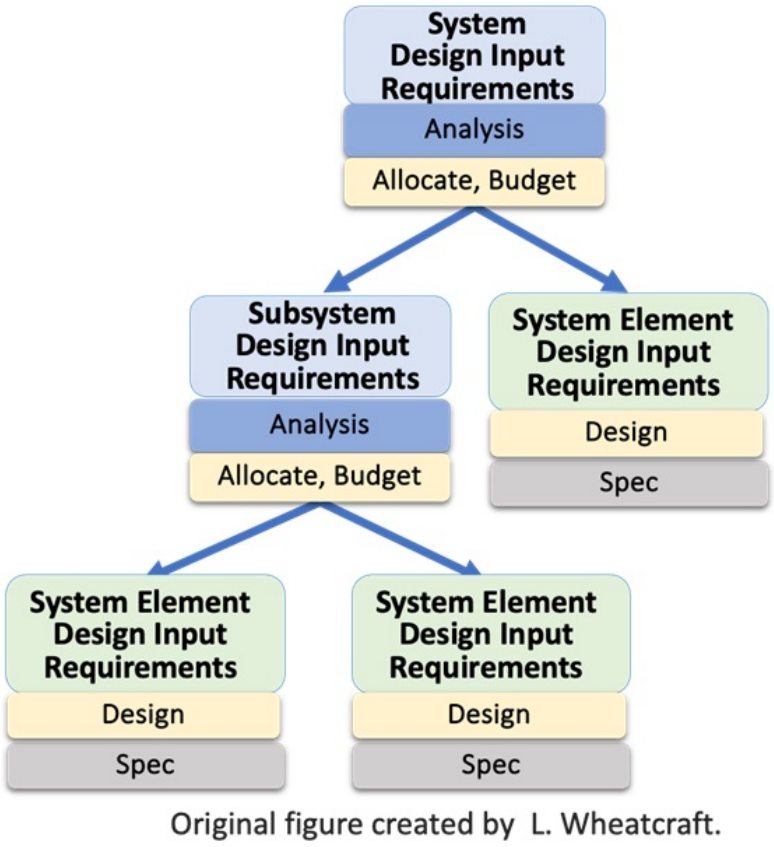

Figure 3. Example Flow of System Requirements with to Lower-level Requirements. This figure is reprinted with permission of Lou Wheatcraft. All other rights are reserved by the copyright owner.

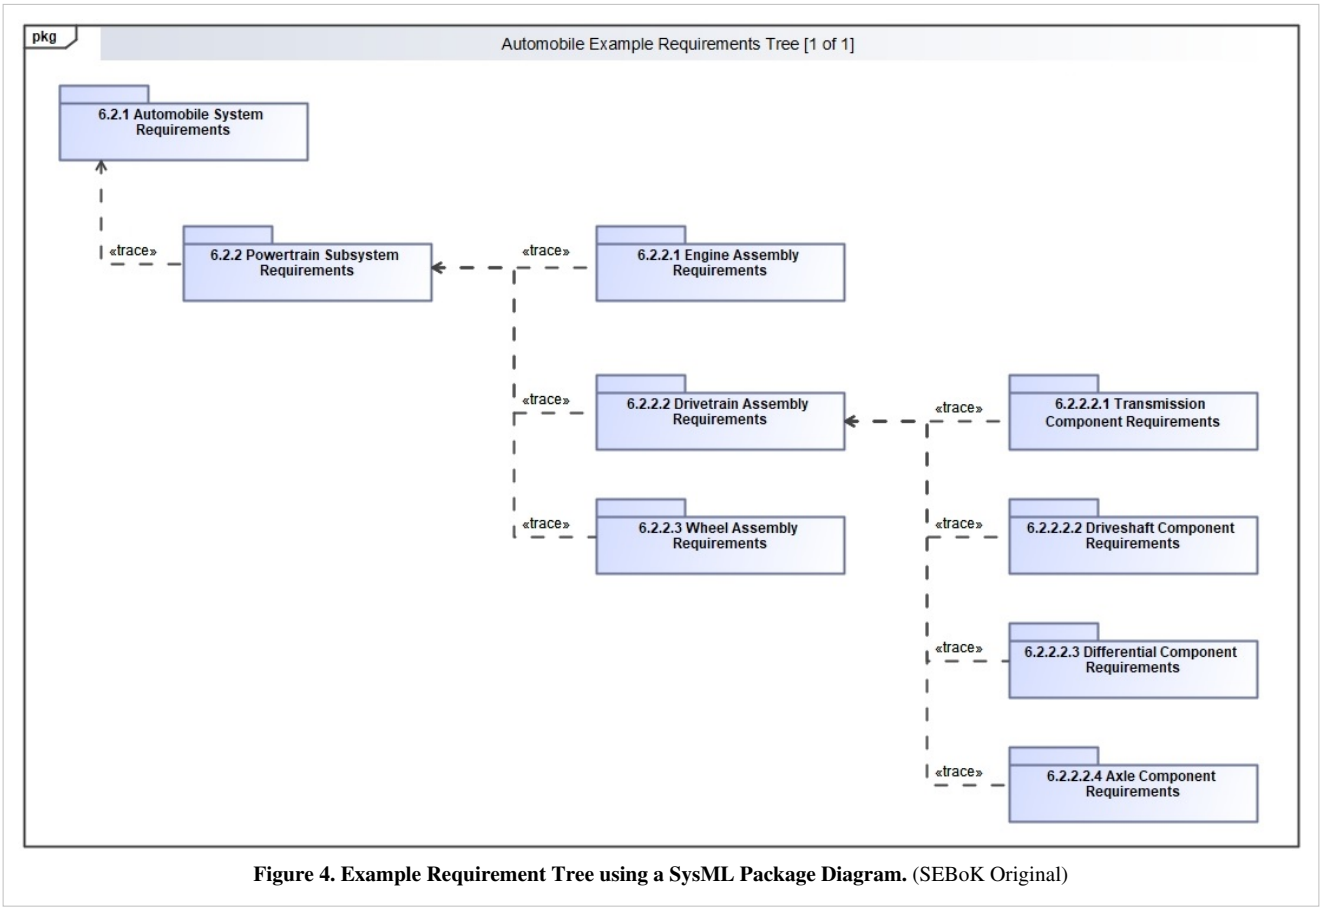

Figure 4. Example Requirement Tree using a SysML Package Diagram. (SEBoK Original)

Allocation is the process by which the requirements at one level of the physical architecture are assigned to those entities at the next lower level of the architecture that have a role in the implementation of the allocated requirement. This involves an analysis where the project team determines what “role”, if any, each subsystem or system element at the next level of the architecture has in the implementation of the requirement being allocated. Requirements generated at the lower level are referred to as child requirements of an allocated parent requirement.

An important concept associated with allocation is budgeting. Budget refers to the total value of a parameter defined at the system level. The system requirement value may be decomposed to ensure the lower-level elements contribute their portion, enabling the system level to achieve its total value. Budgeted quantities result in requirements that have a dependency - a change in one will result in the need to change another. Budgeted values can include mass (weight), power usage, bandwidth, time, and quality attributes).

Principles Governing System Requirements

Addressing Interfaces and Interactions

For each part of the architecture, an external interface diagram provides the ability to address interactions between the SoI and external systems (Figure 5).

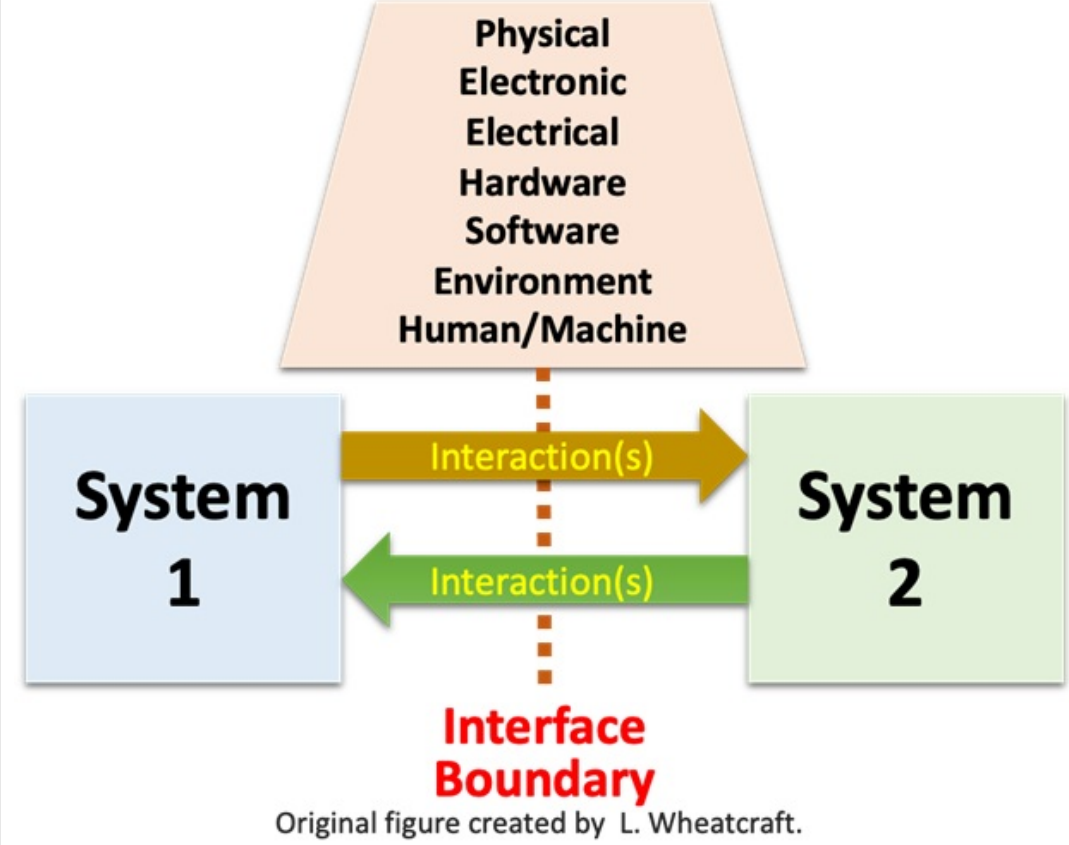

Figure 5. Interfaces Address Interactions between Systems. This figure is reprinted with permission of Lou Wheatcraft. All other rights are reserved by the copyright owner.

The phrase “interface requirement” refers to the specific form or template for a functional requirement that deals with an interaction of a system across an interface boundary with another system. Writing interface requirements is a three-step process (INCOSE NRM 2022):

1. Identify the interface boundaries and interactions across those boundaries.
2. Define the interactions across the interface boundaries (the characteristics of what is crossing the boundary, and media involved).
3. Write the interface requirements.

Example interface requirement:

- The System shall send telemetry to the Ground System as defined in ICD 123, Table X.

Model Form of Requirements

Requirements can be recorded and managed via a document, database, or in the form of a model:

- Models provide the capability to address completeness in terms of functions, inputs to those functions, sources of those inputs, outputs, and customers (destinations/users) for those outputs.
- Models help facilitate communication by making complex systems and processes easier to understand (a picture is worth a thousand words….).
- Models enable the capture of interdependencies of requirements to other aspects of the system dataset, such as inputs, needs, architecture, test cases, etc.
- Models enable quantitative analyses and execution of simulations.

In MBSE, the model form of requirements can be expressed as a diagram (Figure 6) or within a table in the modeling tool (Figure 7), using well-formed textual statements as part of a requirement model element. Refer to Requirements Management for further guidance on usage of tools associated with textual and model requirements.

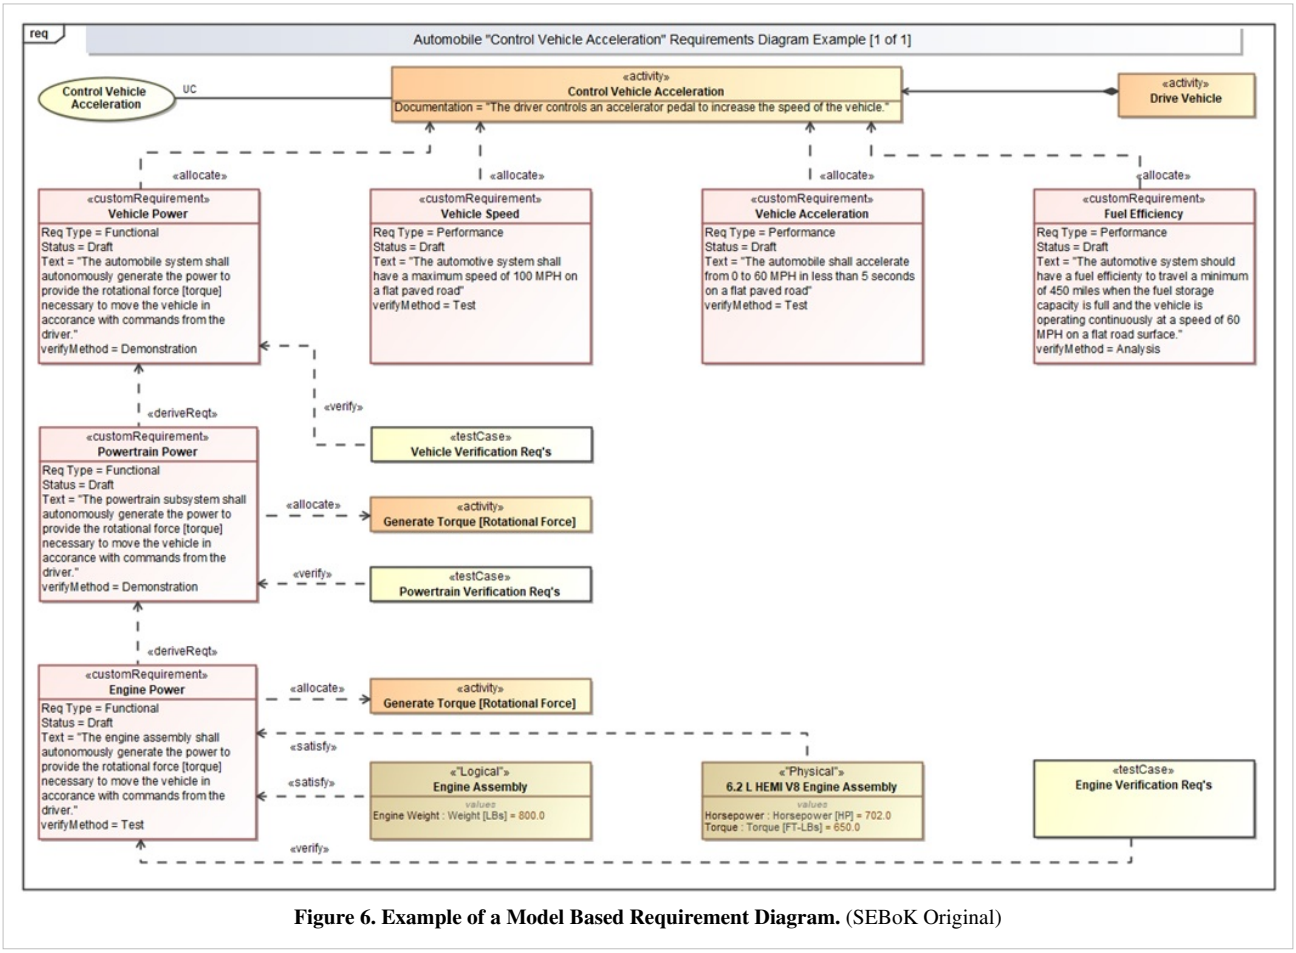

Figure 6. Example of a Model Based Requirement Diagram. (SEBoK Original)

Name	Text Type	Derived From	Req Type	Text	Status	Function Allocation	Satisfied By	Verify Method	Documentation
17 Powertrain Requirements	Header								Powertrain Subsystem Specification
17.1 Powertrain Power	Requirement	12.1 Vehicle Power	Functional	The powertrain subsystem shall autonomously generate the power to provide the rotational force [torque] necessary to move the vehicle in accorance with commands from the driver.	Draft	Generate Torque [Rotational Force]	Engine Assembly 6.2 L HEMI V8 Engine Assembly	Demonstration	
17.2 Powertrain Speed	Requirement	12.2 Vehicle Speed	Performance	The powertrain subsystem shall generate sufficient power to maintain a maximum vehicle speed of 100 MPH on a flat paved road	Draft	Generate Torque [Rotational Force]	Engine Assembly 6.2 L HEMI V8 Engine Assembly	Test	
17.3 Powertrain Acceleration	Requirement	12.3 Vehicle Acceleration	Performance	Te powertrain subsystem shall generate sufficient power to accelerate the vehicle from 0 to 60 MPH in less than 5 seconds on a flat paved road	Draft	Generate Torque [Rotational Force]	Engine Assembly 6.2 L HEMI V8 Engine Assembly	Test	

Figure 7. Example of a Model Based Requirement Table. (SEBoK Original)

Addressing Unknowns

When initially generating a set of requirements, there is often a set of parameters which may require future analysis to determine their actual value. One common method to do this is to use a placeholder in the requirement statement to indicate the requirement is drafted, yet further work is needed before it is considered complete. When a value is unknown, a common approach is to use the "To Be Determined" (TBD) indication within the requirement statement, in place of an actual value. When a value is determined but confidence is low (e.g., feasibility has not been assessed), a method to reflect this is to use the "To Be Resolved" (TBR) indication next to the value. Together, TBRs and TBDs are referred to generically as "TBXs". Keeping track of TBXs allows for awareness of the maturity of the requirements throughout the life cycle and is a valuable metric to evaluate completion and maturity of the integrated set of needs and set of design input requirements.

TBXs can lead to risk if not addressed by the project team prior to significant work in establishing the design solution. TBX management is the process of identifying the TBXs in a requirement set, establishing the work needed to resolve closure of the issue, identifying the owner of the work, and systematically iterating through and completing the actions to enable removal of these placeholders in the requirements.

Traceability

Traceability is a powerful way to manage the design input requirements, especially across levels and across subsystems and system elements within a specific level as well as manage the requirements across the life cycle. Traceability helps ensure the requirements trace to their needs, and that they are correct and complete. Traceability also helps identify allocation of requirements to lower-level system elements of the architecture. Traceability is used to access any impacts of changes to requirements or other types of data across the life cycle, enabling insight into whether that change is beneficial or costly.

Defining a traceability relationship model at the beginning of the project enables an understanding of which relationships will be established and managed via traceability throughout the development of the SoI. An example traceability model is shown in Figure 8 (INCOSE NRM 2022).

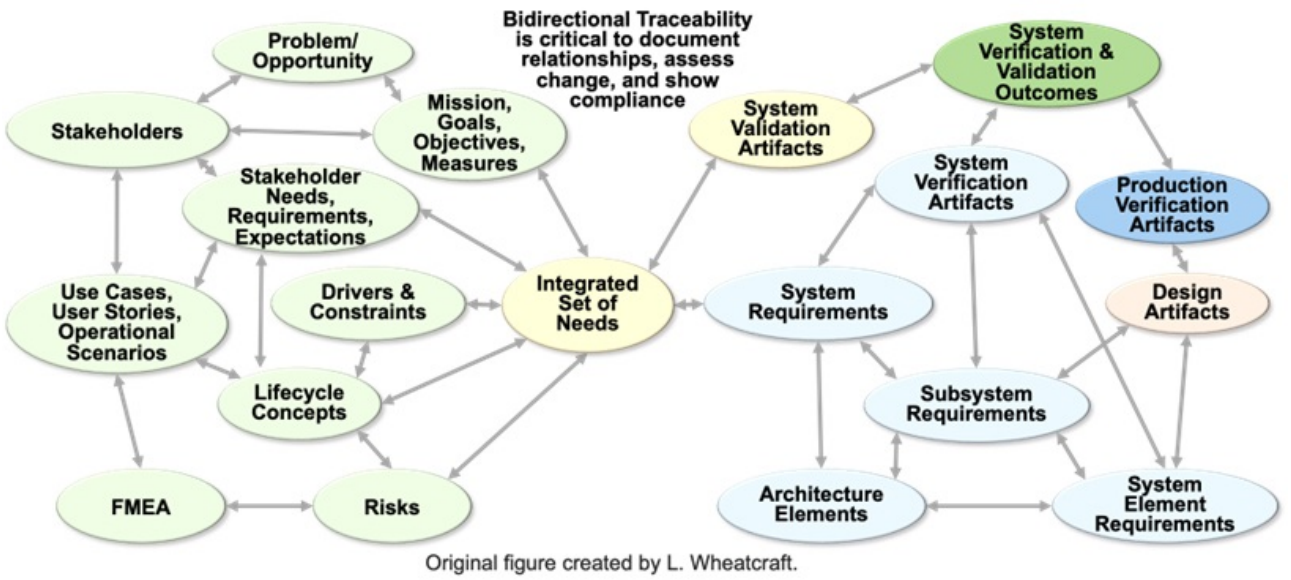

Figure 8. Example Traceability Model. This figure is reprinted with permission of Lou Wheatcraft.

Planning for System Verification

A best practice is to do early planning for how the project will perform system verification. Defining the system verification success criteria, strategy, and method when the requirements are generated helps ensure the requirement statements are worded properly, are within the scope of the project plans, and demonstrate they have the characteristic of "verifiable". This information can be captured within the attributes defined for the requirement.

Assessing the Requirements

Requirements should be assessed to gauge whether they are well-formed and that they meet the intent of the needs from which they were transformed. Concepts behind assessment of the requirements are captured with the terms "requirement verification" and "requirement validation", which are not the same concepts described for system verification and system validation.

- Requirement verification activities address: Are the requirements well-formed, i.e., do the individual requirements and sets of requirements have the characteristics and follow the rules defined in the organizations criteria for well-formed requirements?
- Requirement validation activities address: Do we have the right requirements, i.e., do the requirements clearly communicate the intent of the needs, parent requirements, and other sources from which they were transformed, in a language understandable by the architectural definition, design definition, and manufacturing/coding teams? Validation addresses if the requirements are correct and are also achievable.

There are several methods that can be used to verify and validate requirements, such as standard peer review techniques and comparison of each requirement against a set of requirements characteristics and the integrated set of needs. For requirements communicated in a textual form, guidelines exist for writing well-formed requirements; they include recommendations about the syntax of requirements statements, wording (exclusions, representation of concepts, etc.), and characteristics (specific, measurable, achievable, feasible, testable, etc.) (INCOSE GtWR 2023).

System Requirement Definition Artifacts

The System Requirements Definition process results in a variety of artifacts:

- well-formed requirements recorded in models, databases, or documentation,
- requirement tree,
- traceability of requirements to other data,
- defined interactions across boundaries,
- performance budgets, and
- initial system verification plans.

Requirements Management

Requirements Management (RM) is performed to ensure alignment of the system, subsystem, and system element requirements with other representations, analyses, and artifacts of the system across the life cycle. It includes providing an understanding of the requirements, obtaining commitment, managing changes, maintaining bi-directional traceability among the requirements and with the rest of the system definition, and alignment with project resources and schedule. The Requirements Management article provides additional guidance on methods for performing requirements management.

The system architecture design defines system behavior and structure characteristics in accordance with derived requirements. The architecture ensures that the system elements operate together in the applicable operating environment to satisfy Stakeholder needs. Figure 1 illustrates the system design phenomenon based on Hamilton's Principle: a system is composed of interacting elements exchanging data, energy, or mass to impact the state of cooperating elements resulting in continuous, discrete, or emergent behaviors at progressive levels of aggregation or decomposition.

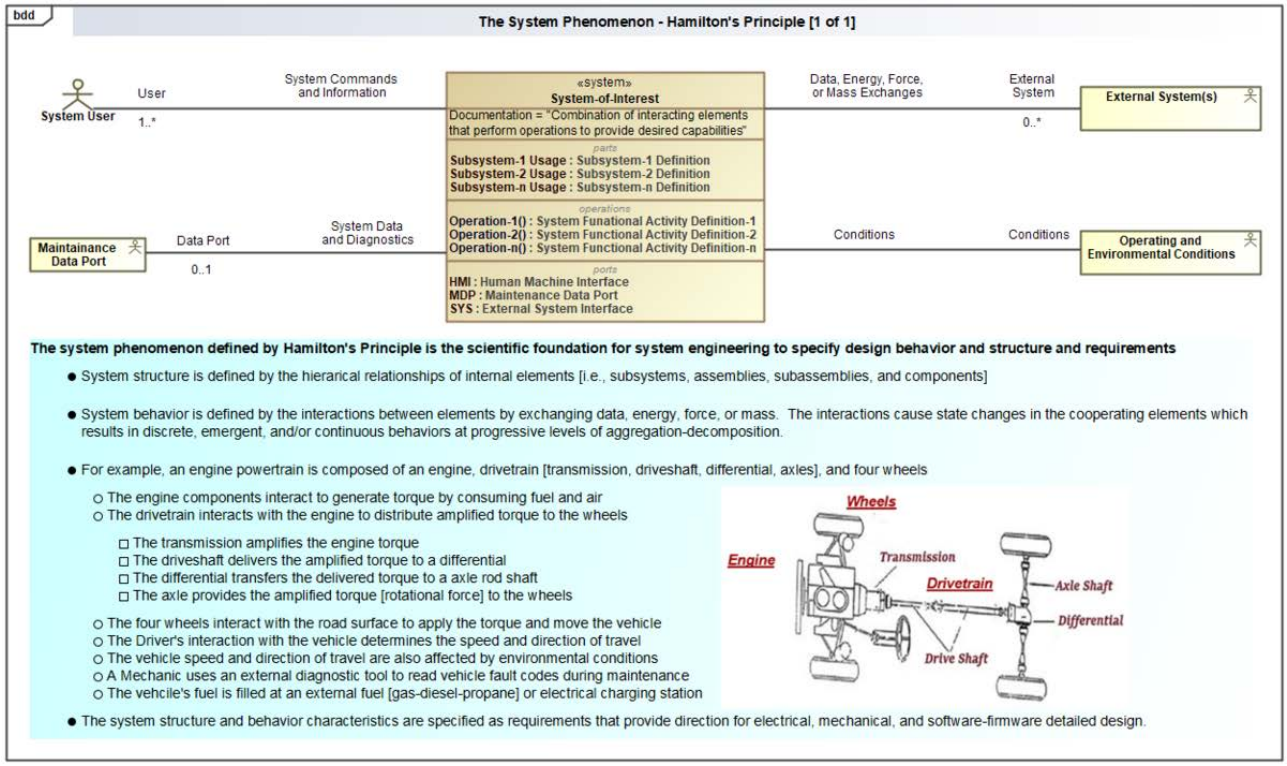

Figure 1. The System Phenomenon – Hamilton's Principle (SEBoK Original)

Systems Engineering has traditionally applied intuitive domain-specific [e.g., aerospace, defense, automotive, consumer, …] product practices emphasizing processes and procedures. The practices in conjunction with proficient

writing skills manually organize design configuration information in a disparate collection of documents. The documents depict the system architecture design with textual description and graphical figures using unique organizational adopted notation without formal semantics. The documents require manual updating to synchronize design configuration information resulting in consistency issues in addition to cost and schedule inefficiencies.

This article describes a model-based system architecture design definition approach with the Systems Modeling Language [SysML] for product development, integration, and verification. This approach enables digital transformation design initiatives to employ Model-Based System Engineering [MBSE] practices similar to other design engineering disciplines [EE, ME, SW].

SysML provides industry standard graphical and textual [added with SysML-v2] notations with formal semantics to define system design requirements, behavior and structure characteristics with traceability to the associated requirements. The system design model provides an Authoritative Source of Truth [ASoT] digital repository of the project technical baseline including requirement, functional, logical, and physical design representations for each system, subsystem, and component design abstraction level. Integrated system design model simulation capabilities with verification criteria of end-to-end system "digital threads" enable evaluation of key performance parameters to verify design decision or discover and resolve design defects in digital environments. The system design model with integrated simulation capabilities provides a system "digital twin" as an authoritative representation of the physical system including digital thread end-to-end simulations with all the data, models, and infrastructure necessary to optimize the system design digitally and explore design alternatives for system improvements to evolving missions and threats. The approach is tailorable to satisfy specific project objectives.

System Architecture Design Overview

System architecture design definition includes system behavioral and structural analyses to define a holistic technical solution that satisfies Stakeholder needs. The model-based system architecture design definition approach provides an implementation for the ISO/IEC/IEEE-15288 Architecture Definition technical lifecycle process. The approach defines practices to develop, integrate, and employ digital system design models for cross-domain collaboration by applying product domain-specific design knowledge and expertise.

The system architecture design defines the structural elements and their behavior interactions in the applicable operating environment to satisfy Stakeholder needs. The architecture includes a project overview with representations of system requirements, functional behavior & interactions, logical and physical configuration items. Figure 2 illustrates the system architecture design definition approach.

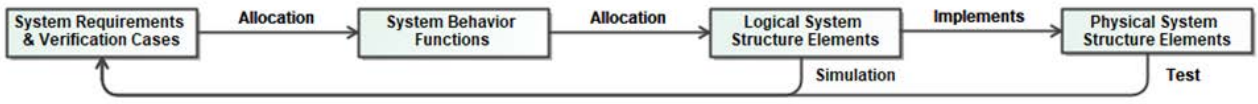

Figure 2. System Architecture Design Definition Approach. (SEBoK Original)

The following describes the model-based system architecture design definition approach activities and information for the digital system design model.

1. Provide a project overview by describing the scope of the project and the system/project boundaries.
    1. System mission description relative to the project's Stakeholder needs with requirements traceable to the system needs.
    2. Glossary of terms with descriptions of the design model organization, environment, development approach, SysML conventions and custom profiles
2. Define the system requirements and verification criteria derived from the Stakeholder Needs to specify the system capabilities, functions, interfaces, performance, characteristics, operating conditions and environments.

1. System use cases reflect black-box functionality, solution constraints, boundaries, external human and system interfaces.
2. Capabilities and requirements derived from the Stakeholder's needs verified with engineering analysis, demonstration, inspection, and test results throughout the hierarchical system structure of elements.

3. Define the system functional hierarchical functions and subfunctions with their behavior interactions to satisfy Stakeholder needs. Each function defines input-to-output transformations to satisfy one or more allocated requirement(s).
   1. System use case elaboration identifies system capabilities with activity, sequence, and state machine diagrams to describe system functional operations decomposed into User tasks, system functions and subfunctions with the associated requirements and verification criteria.
   2. System element interactions define how the functions and subfunctions operate together via interfaces to provide capabilities.
4. Define the logical system structural elements to identify logical configuration items without a specific design implementation, referred to as the technology Platform Independent Model [PIM]. Each logical configuration item has a set of allocated functions and subfunctions with specified property attributes, interfaces, and functional performance requirements for programmatic make vs. buy decisions. Also, each logical element has a corresponding physical design element with additional lower-level design details. For example, an automobile design will specify a logical combustion engine with requirements to establish a contractual baseline for production/procurement.
   1. Recursive white-box analyses identify logical configuration items with allocated functions, subfunctions, and interfaces for implementation by the corresponding physical configuration item.
   2. Logical configuration items include hierarchical subsystems, assemblies, subassemblies, and components based on the system complexity.
5. Define he physical system structural elements to identify a specific design implementation for each logical structural element, referred to as a technology Platform Specific Model [PSM]. The physical configuration items comply with the allocated requirements and have a specific manufacturer's part number identification. For example, an automobile will have a specific V8 gas, diesel, or propane combustion engine in accordance with the requirements and include additional physical engine component configuration items [e.g., pistons, spark plugs, cam shaft, ...].
   1. Recursive design analyses with electrical, mechanical, and software engineering to identify the specific design implementation for physical configuration items [i.e., manufacture and part number identification].
   2. Physical configuration items provide a design implementation for the corresponding logical element including the required property attributes and functional operations.

System Architecture Design Definition Model

Figure 3 provides an example for the organization of the digital system design model. The design model provides an Authoritative Source of Truth [ASoT] repository for a project's system technical baseline including requirements, functional, logical, and physical design representations for each system, subsystem, and component design abstraction level. The design model also provides design libraries for product-line management and reuse.

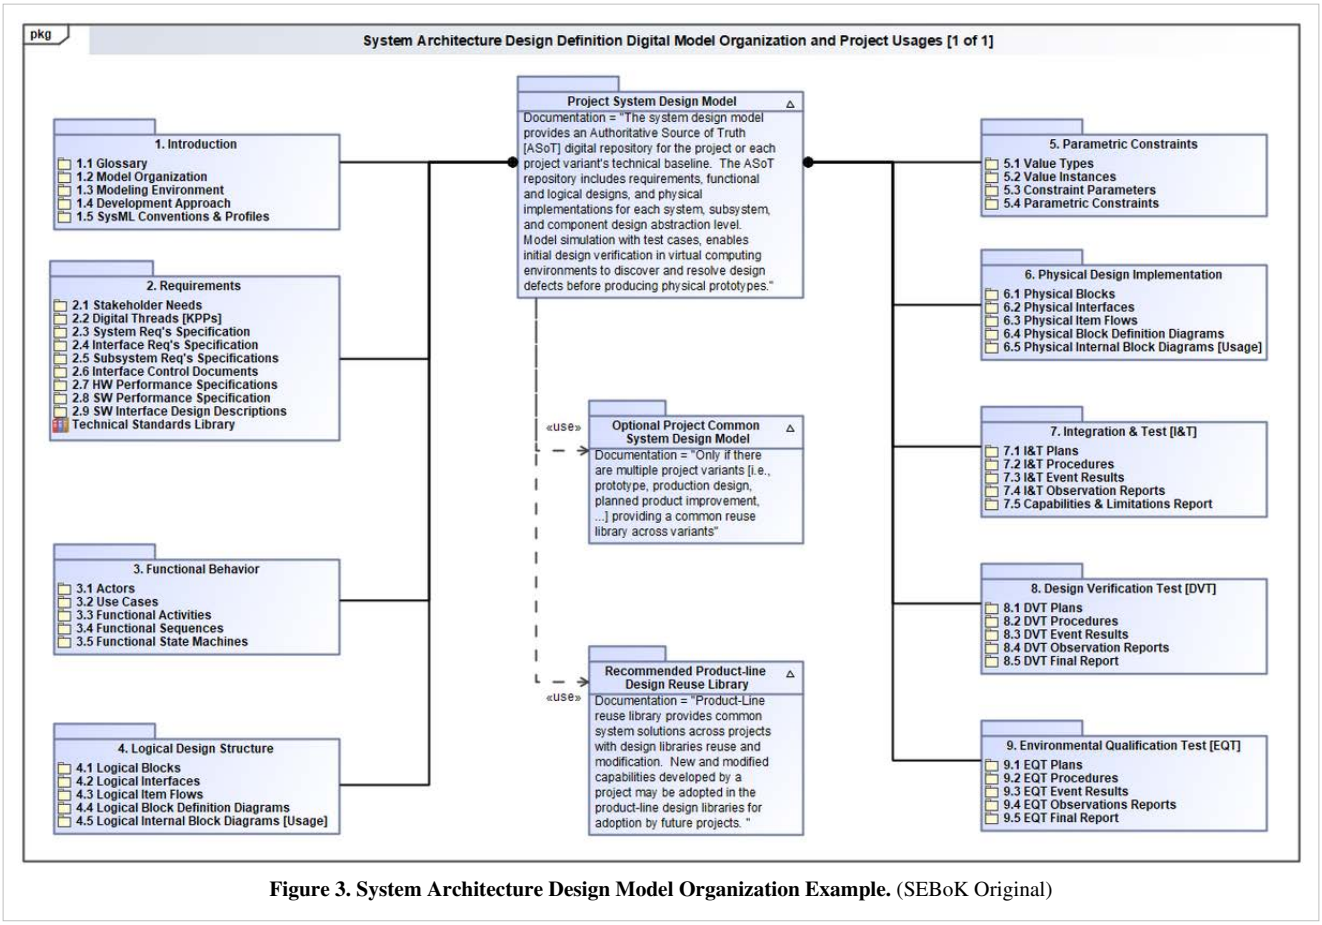

Figure 3. System Architecture Design Model Organization Example. (SEBoK Original)

The digital system design model enables the following:

- Specifies system behavior and structure characteristics with traceability to the associated requirements.
- Provides an Authoritative Source of Truth [ASOT] digital repository of a project's approved technical baseline across engineering, production, and sustainment including requirement, functional, logical, and physical design representations for each system, subsystem, and component design abstraction level for collaboration and decision making.
- Provides product design libraries to adapt product designs to stakeholder needs with new, modified, and existing system capabilities.
- Integrated system design model simulation capabilities with verification test cases of end-to-end system "digital threads" enable evaluation of key performance parameters to verify design decision, discover and resolve design defects in digital environments before the expense of producing prototypes.
- Assessment of design changes in all model usages for compliance, with any issue(s) flagged for corrective action.
- Provides a system design model with integrated simulation capabilities providing a system "digital twin" representing an authoritative representation of the physical system including digital thread end-to-end simulations with all the data, models, and infrastructure necessary to optimize the system design digitally and explore design alternatives for system improvements to evolving missions and threats.
- Provides design model scripts to export functional & interface specifications, design & requirements traceability and design descriptions reports.

System Architecture Design Definition Model Viewpoints and Views

The architecture model includes multiple views of the system design features with the information necessary to address each stakeholder's viewpoint and concerns. Figures 4a and 4b provide typical system views and viewpoints which are tailorable by specific projects, if necessary.

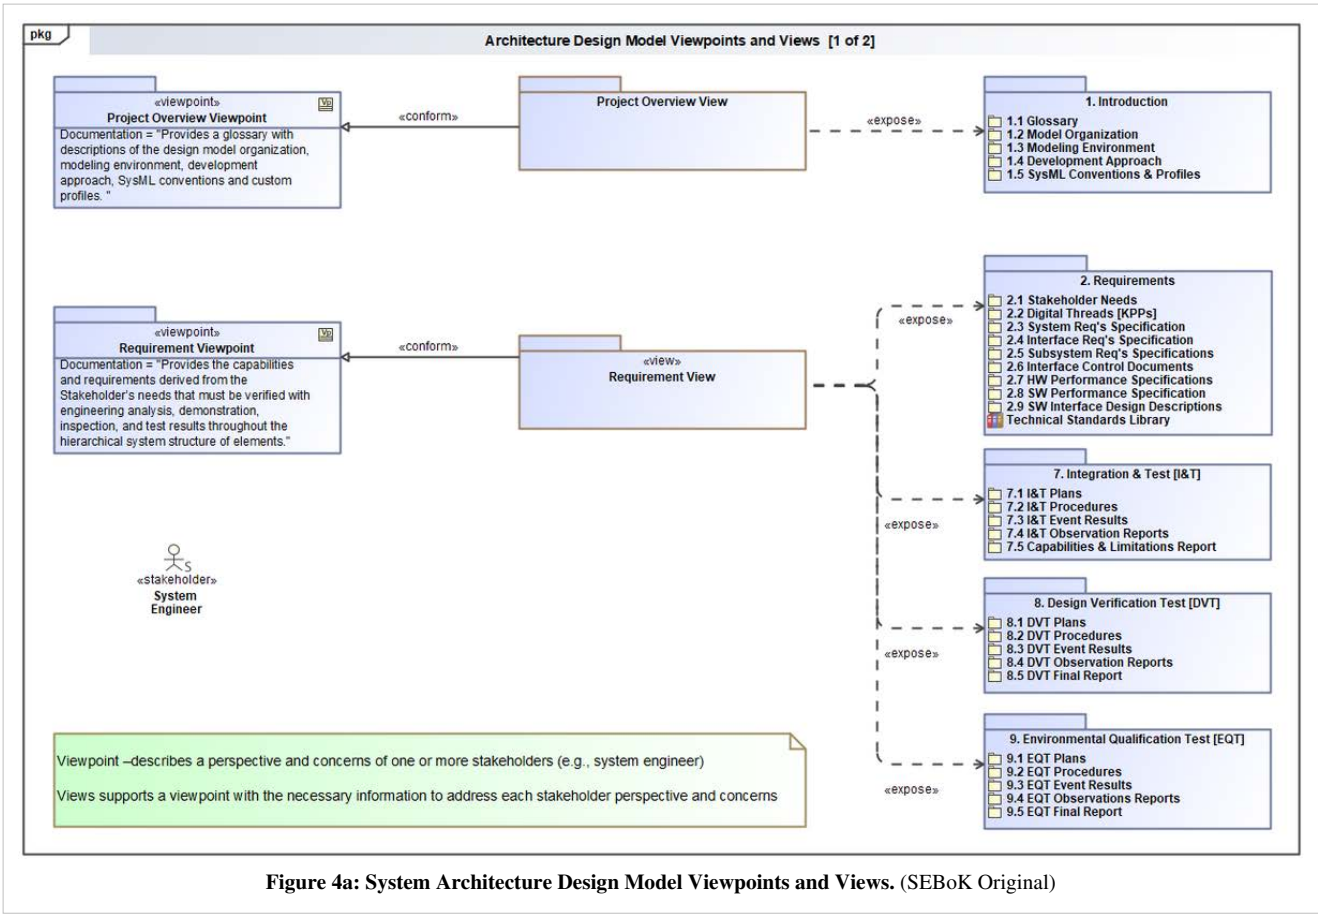

Figure 4a: System Architecture Design Model Viewpoints and Views. (SEBoK Original)

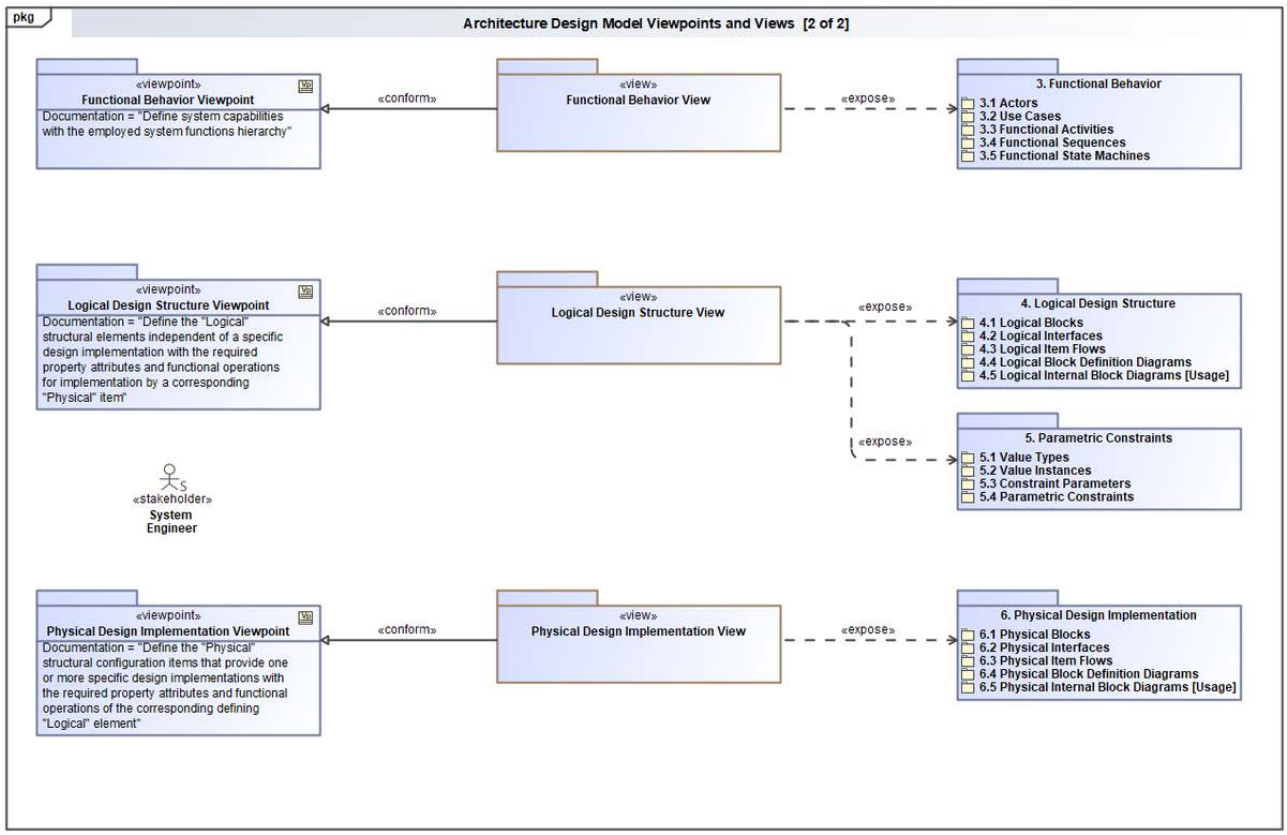

Figure 4b: System Architecture Design Model Viewpoints and Views. (SEBoK Original)

System Architecture Design Definition Modeling Ecosystem

Digital system design model integration within an engineering development ecosystem including electrical, mechanical, software and specialty engineering models enables system-level simulations. The system simulations provide initial design verification in digital environments to discover and resolve design defects before producing physical prototypes. Figure 5 provides an example of a model-based system design ecosystem.

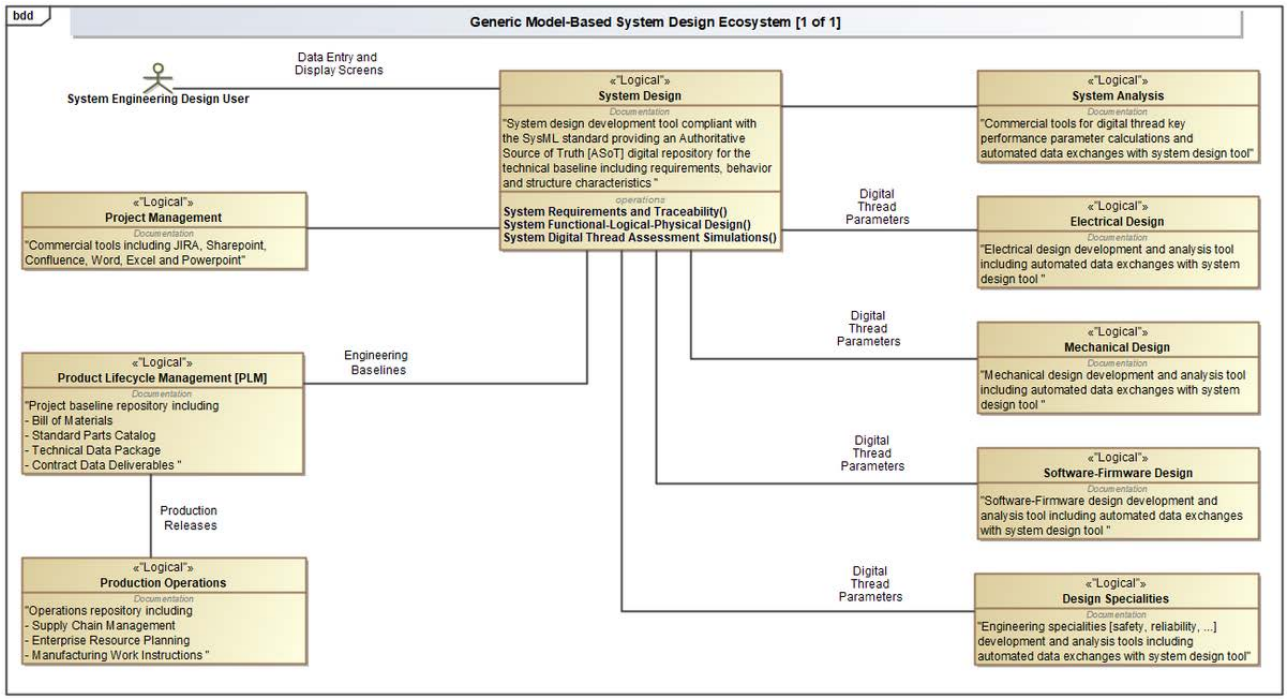

Figure 5. Model-based System Design Ecosystem Example. (SEBoK Original)

The digital system design model provides an executable representation of a system in terms of the hierarchical structural elements and their behavior interactions to satisfy Stakeholder needs in the applicable operating environment.

- Hierarchical structural elements include subsystems, assemblies, subassemblies, and components enabling separation of concerns between each design abstraction level.
- Element interactions involve the exchange of data, energy, force, or mass that trigger state changes in the cooperating elements resulting in discrete, emergent, or continuous behaviors at progressive levels of aggregation or decomposition.

The executable design model enables digital simulations to confirm system functional performance, accuracy, timeliness, and stability with verification criteria. In addition, the system response to operating condition variations is evaluated including deterministic and stochastic disturbances to discover design defects and enhancements before the expense of producing physical prototypes. The governing principle is to develop digital system design models with high-fidelity simulation capabilities to realistically emulate systems to create a digital twin with digital threads to evaluate design alternatives in virtual computing environments without producing prototypes as shown in Figure 6.

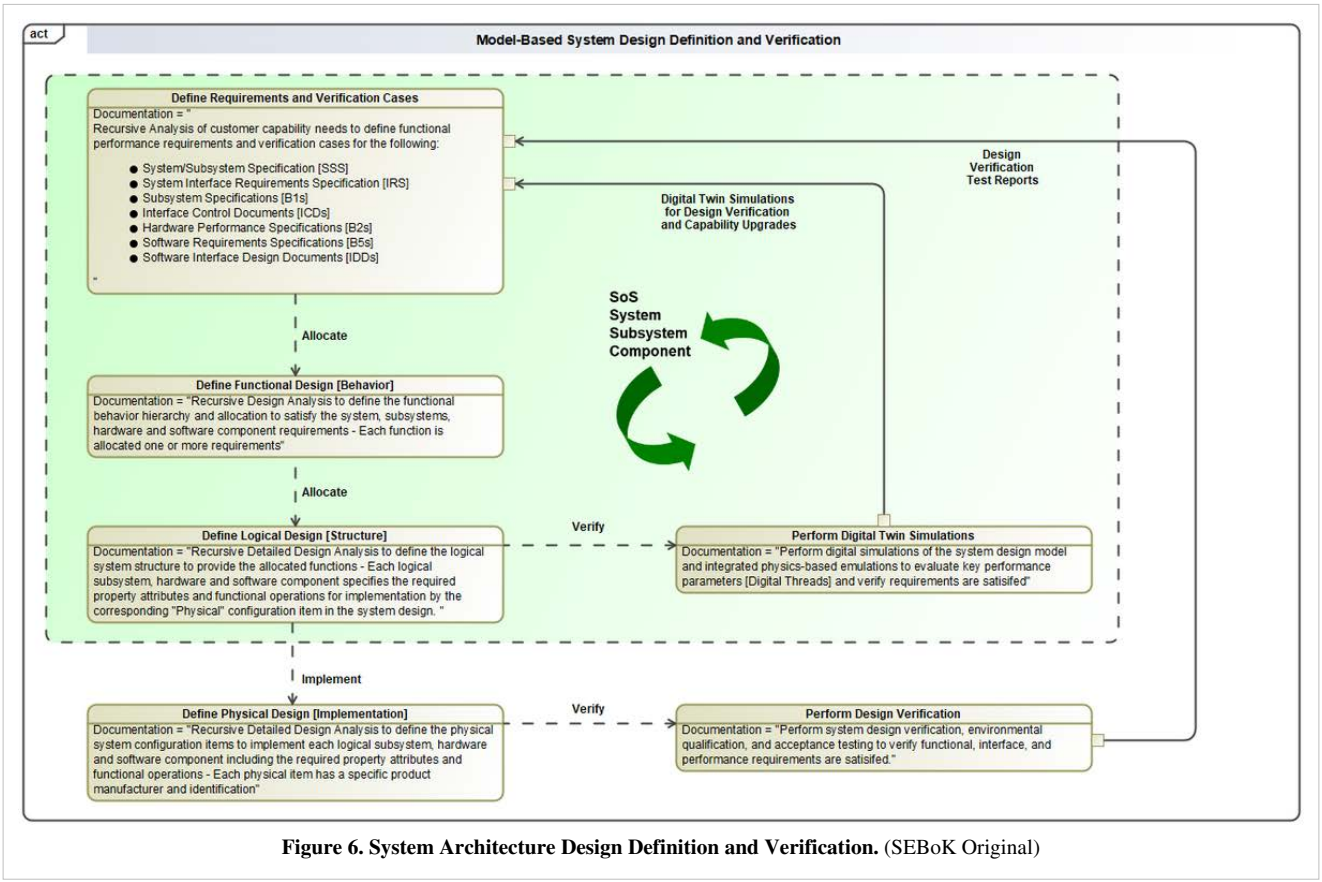

Figure 6. System Architecture Design Definition and Verification. (SEBoK Original)

- Digital threads are analytical frameworks providing end-to-end system simulation representations to evaluate key performance parameters in virtual environments by exchanging information between different modeling tools across the lifecycle.
- Digital twins are authoritative representations of physical systems including the digital thread end-to-end connections with all the data, models, and infrastructure needed to create and optimize a system's lifecycle digitally. Digital twins enable project team collaboration, system simulation performance assessments, design change impact evaluations, and product-line management reuse libraries.

System Architecture Design Definition Illustrative Example

Figure 7 provides an example automobile product to illustrate how the digital design model can specify, analyze, and design the system. The scope of the example is an automotive powertrain subsystem consisting of an engine, drivetrain, and four-wheel assemblies. The drivetrain assembly consists of transmission, driveshaft, differential, and two axle shaft rod subassemblies. The intent is to demonstrate the system architecture design definition approach and design solution accuracy is not a high priority.

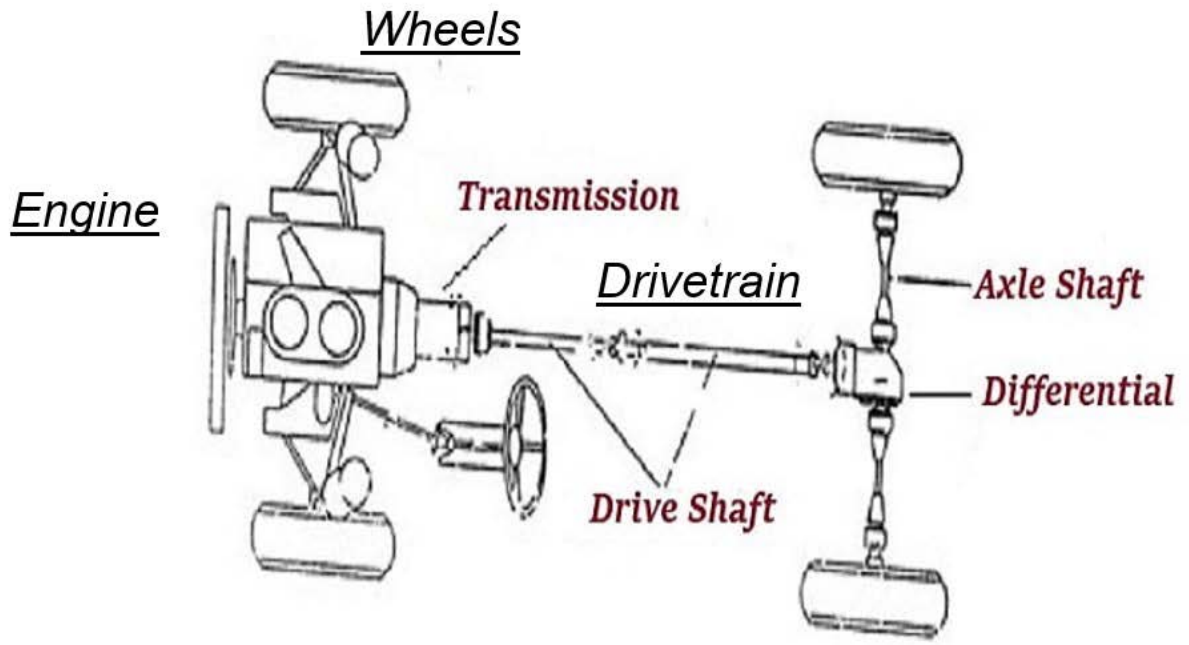

Figure 7. Automobile Product Design Example. (SEBoK Original)

Figure 8 provides the automobile system context and use cases. The diagram defines the automobile system boundary, Stakeholder capability needs, and external interfaces with. The design analyses will focus on the "Drive Vehicle" capability which includes the "Control Vehicle Acceleration" function allocated to a logical and physical system "Powertrain" subsystem.

- The powertrain subsystem is composed of engine, drivetrain, and wheel assemblies.
- The engine assembly components interact to generate torque by consuming fuel and air.
- The drivetrain assembly is composed of transmission, driveshaft, differential, and two axle rod shaft subassemblies. The drivetrain interacts with the engine to distribute amplified torque to the wheels.
  - The transmission subassembly amplifies the engine torque.
  - The driveshaft subassembly delivers the amplified torque to a differential.
  - The differential subassembly transfers the delivered torque to axle rod shaft.
  - The axle shaft rod subassembly provides the amplified torque [rotational force] to the four wheels.
- The four-wheel assemblies interact with the road surface to apply the torque and move the vehicle.
- The Driver's interaction with the vehicle determines the speed and direction of travel.
- The vehicle speed and direction of travel is affected by environmental conditions.
- A Mechanic uses an external diagnostic tool to read vehicle fault codes during maintenance.
- The automobile's fuel is filled at an external fuel [gas-diesel-propane] or electrical charging station.

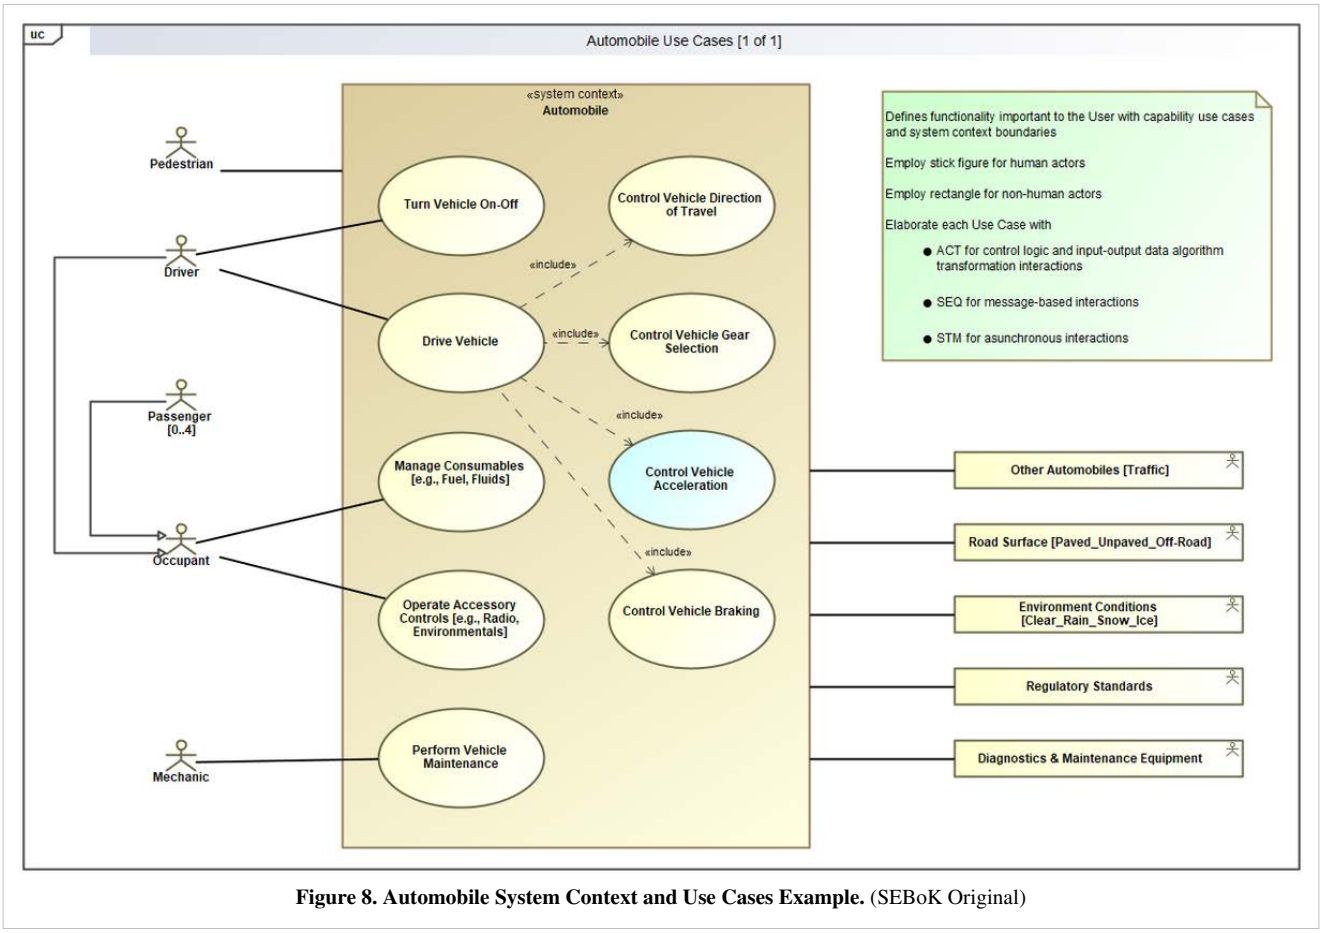

Figure 8. Automobile System Context and Use Cases Example. (SEBoK Original)

The following three sub-articles [functional, logical, and physical architecture] illustrate the model-based system architecture design definition approach for the automobile system example to define a holistic solution. The functional architecture article has been provided. The logical and physical architecture articles will be updated in future SEBoK releases.

Functional Architecture

- Lead Authors:
- Caitlyn Singam and Jeffrey Carter

-

A system's functional architecture is the inter-related set of transformative processes and purposeful input-output tasks (i.e., functions) that a system performs, or can perform, on input(s) from external or internal sources in order to produce output(s) that supports the achievement of mission objectives. More simply, functional architecture defines the various actions a system can perform in support of specific goals, and how those actions relate to each other in order to collectively give the system the appropriate capabilities to meet those goals. The handling of internal inputs and outputs (such as those generated by and passed between sub-functions) are encompassed in functional architecture as well.

Since a system's functional architecture only defines the system in relation to transformative functions and their inputs/outputs, it is not in and of itself a complete definition of all aspects of the system design. Functional architecture is thus considered as an architectural "view" or "perspective", rather than as a standalone sub-unit of the overall system architecture. Other system architectural views, such as logical architecture and physical architecture, can be used to provide limited context for a given system's functional architecture without the need to examine all aspects of a complete system architecture.

Functional architectures are typically represented via abstract system models when used as part of documentation capturing and/or defining the characteristics and behaviors of a system of interest. Capturing a system's functional architecture is a key part of system architecture design definition and is typically done early on in a system's life cycle. The closely associated task of functional architecture modeling is generally performed at the same time and in advance of any system development efforts, though there are instances (e.g., in studies of natural systems) where there may be an interest in documenting the functional architecture of a system already in operation. Once developed, functional architecture models provide a useful means of elucidating the processes which underlie a system's abilities and behaviors to stakeholders, and consequently can be used later on in the system life cycle as well, in support of verification and validation (V&V) efforts and system design review activities.

This article discusses how functional architecture relates as a concept to other facets of system architecture, and discusses key principles related to the development and documentation of functional architecture in practice.

Purpose

The purpose of functional architecture is essentially stated directly in the name: it defines what functions and sub-functions exist within a system of interest (SoI), and the metaphorical "layout" or architecture which connects or otherwise relates these functions. Specifically, these function definitions involve the identification of the system's inputs and outputs (both main and intermediary), and the expression of system activities in terms of the actions they perform, either directly or in association with auxiliary system processes, to transform those inputs into output elements and behavioral outcomes (ISO/IEC/IEEE 15288:2023). The idea of a "function" in the specific context of functional architecture is thus arguably closer to how it is used in mathematics (in the sense of "y is a function of x") or computer programming than in other aspects of systems engineering, where "function" takes on a broader definition generally along the lines of actions performed in pursuit of a desired outcome (Hitchins 2008) and not directly tied to input-output transformations.

Relation to Behavioral Architecture

Functional architecture is distinct from the closely related concept of behavioral architecture, which it can be easily conflated with due to the similar technical meanings of the terms "behavior" and "function". Both functional and behavioral architecture concern purposeful actions undertaken by a given system, and the manner in which those actions enable the production of observable features such as system modes and mode transitions, but differ in terms of the lenses through which they view and define the system's actions.

Functional architecture relates to input-output transformations: the manner in which a system operates on, and/or in relation to, intangible and tangible inputs from the entities, users, and environments which exist around it in the surrounding system context through the transformation of inputs into outputs. Behavioral architecture, in contrast, is more concerned with the sequencing and execution of system actions, and how system actions interact with checkpoint conditions and the initiation/completion of other system tasks in order to produce behavior.

Application in practice

An overall system architecture is generally defined very early on in the system life cycle, as it plays a key role in translating the system concept definition into a viable system design (INCOSE 2023). Functional architecture, as one of many potential "views" of that system architecture, offers a lens through which one can consider the system in question in order to ensure that key elements of the system architecture are not omitted or overlooked, and to furthermore ensure that changes in aspects of the system architecture that were defined outside the scope of the functional view do not conflict or otherwise cause issues with the system's functionality.

The functional architecture view of a completed system architecture should, at minimum, define the following:

1. the functional capabilities that the system uses to fulfill mission objectives and meet stakeholder needs;
2. the required inputs and outputs for those system functions;
3. the steps through which the system will transform provided inputs into the desired outputs;
4. the grouping of those steps into independently executable sub-functions, if sub-functions are being employed, with corresponding definitions of the inputs and outputs for those sub-functions;
5. the variations in the inputs, outputs, and execution of the system's function/sub-functions for each system mode, if the system has multiple modes; and
6. the internal and external interfaces enabling input flow and output flow for each defined function, sub-function, and auxiliary function.

Given that functional architecture is merely a partial "view" of the overall system architecture, it is generally a good practice to consider a system's functional architecture in juxtaposition with other architectural views for context. Logical architecture, physical architecture, and functional architecture are often discussed in conjunction with each other (Pineda and Smith 2010; Borky and Bradley 2019; Stief et al. 2018) since they provide distinct but mutually relevant perspectives of how the system's capabilities are implemented in a given system design (Broy et al. 2009). Taken together as a trio, they provide a fairly comprehensive portrait of the overall system architecture, and can be as key lenses through which to develop design concepts for new systems or examine the architecture of pre-existing ones. Figure 1 provides the functional architecture viewpoint and view within the system design model.

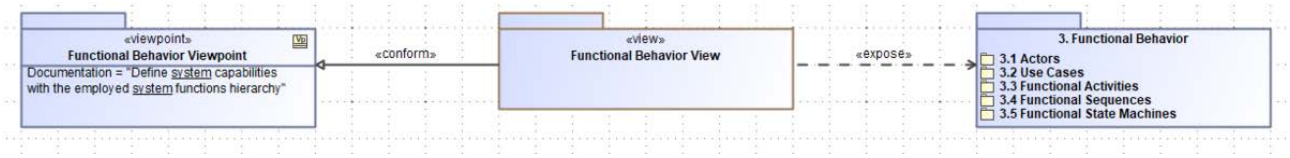

Figure 1. Functional Architecture Viewpoint and View expressed in SysML. (SEBoK Original)

Modeling

A system's functional architecture is an abstract concept; consequently, while it might be possible to deduce the functional architecture of an existing system through observation and testing of the system while it is in operation (as might be necessary when examining/documenting a natural system), doing so is generally a non-trivial, time-intensive task. Thus, a model of a system's functional architecture, which provides a representation of the system's functionality in a manner that can be accessed and understood by relevant parties, is a useful means through which individuals can interact with information about system's functional architecture concept. It is worth noting, however, that a functional architecture model is not equivalent to the system's functional architecture itself: while a system's functional architecture refers to the conceptual idea of how a system transforms its inputs into outputs, a functional architectural model serves as a representation or expression of that concept to communicate understanding of the system's functionality. As with any model, a functional architectural model will not necessarily capture every possible nuance of what is being modeled, and in cases where one is attempting to model the functional architecture of a system without complete knowledge of the system requirements, etc. that impacted the details system's functionality (natural systems again being an example of this), it is entirely feasible to have a functional architecture model that does not match the functional architecture of the system. The terms "functional architecture view" and "functional architecture model" should thus not be used interchangeably as the former refers an idea (a specific aspect of the overall system architecture), and the latter to a representation used to communicate the key aspects of that idea in a manner that may be imperfect and/or incomplete.

There are multiple options for how one can express a system's functional architecture in model form. The optimal type of model for representing any one given system's functional architecture is something that is usually best assessed on a case-by-case basis depending on the system and scope of the model's intended use. Text-based descriptive architecture models, for instance, are suitable solutions for systems with straightforward functional architectures that only involve a few functions and inputs/outputs since those architectures can be described in paragraph form without too much difficulty. In cases where the functional architecture involves a large number of conditional operations or highly interconnected processes, a visual diagram-based model (Youngs et al. 1999) or digital software model (Lemazurier, Chapurlat, and Grossetête 2017; Brinkkemper and Pachidi 2010) are likely to be preferable to text-based descriptions in terms of accurately representing the full gamut of system functionality while still making it feasible to extract information from the model without undue effort (Nowodzienski and Navas 2023; Younse, Cameron, and Bradley 2021). The principles of model-based systems engineering (MBSE) tend to be useful in ensuring the development of a quality system architecture model, and it is thus recommended for individuals to apply such principles when performing architecture modeling in various contexts (Estefan 2007; Kaslow et al. 2017). Software packages for generating digital MBSE-friendly models sometimes include tools that automatically check the model for errors (e.g., incorrectly expressed data flows), which can be useful when modeling informational flow through system functions.

For individuals using Unified Modeling Language (UML), Systems Modeling Language (SysML), or other standardized graphical modeling approaches to express their system concept, the functional architecture and behavioral architecture views are often considered and evaluated jointly due to their coordinated expression in SysML diagrams. Figures 2-5 are presented below for the reader's edification as illustrative exemplars of some of the diagram types of relevance in a functional architecture view of a SysML model, including a Use Case Diagram for a system (Figure 2), a Block Definition Diagram of hierarchical system functions (Figure 3), an Activity Diagram describing an individual system function (Figure 4), and a State Machine Diagram of the overall system (Figure 5). The diagrams below are presented in the example context of an automobile powertrain application.

Logical Architecture Model Development may be used as a task of the activity "Develop candidate architectures models and views," or a sub-process of the System Architecture Design Definition process. Its purpose is to elaborate models and views of the functionality and behavior of the future engineered system as it should operate while in service. The logical architecture model of a engineered system of interest (SoI) is composed of a set of related technical concepts and principles that support the logical operation of the system. It may include a functional architecture view, a behavioral architecture view, and a temporal architecture view. Other additional views are suggested in architecture frameworks, depending on the domain.

Note: The term *Logical Architecture* is a contraction of the expression *Logical View of the System Architecture*.

Concepts and Principles

Functional Architecture Model

A functional architecture model is a set of functions and their sub-functions that defines the transformations performed by the system to complete its mission.

Function and Input-Output Flow - In the context of System Architecture, functions and input-output flows are architecture entities. A function is an action that transforms inputs and generates outputs, involving data, materials, and/or energies. These inputs and outputs are the flow items exchanged between functions. The general mathematical notation of a function is $\mathbf{y} = f(\mathbf{x}, t)$, in which **y** and **x** are vectors that may be represented graphically and t = time.

In order to define the complete set of functions of the system, one must identify all the functions necessitated by the system and its derived requirements, as well as the corresponding inputs and outputs of those functions. Generally speaking, there are two kinds of functions:

1. Functions that are directly deduced from functional and interface requirements. These functions express the expected services of a system necessary to meet its system requirements.
2. Functions that are derived and issued from the alternative solutions of the physical architecture model and are dependent upon the result of the design; additionally, they rely upon on technology choice to implement the logical architecture model elements.

Functional Hierarchy/Decomposition of Functions - At the highest level of a hierarchy (Figure 1), it is possible to represent a system as a unique, central function (defined as the system's mission) that in many ways is similar to a "black box" ("F0" in plan A-0 in Figure 1). In order to understand, in detail, what the system does, this "head-of-hierarchy" (F0) is broken down into sub-functions (F1, F2, F3, F4) grouped to form a sub-level of the hierarchy (plan A0), and so on. Functions of the last level of a functional hierarchy can be called leaf-functions (F21, F22, F23, F24 in plan A2). Hierarchies (or breakdowns) decompose a complex or global function into a set of functions for which physical solutions are known, feasible, or possible to imagine.

This view of functional hierarchy represents a static view of functions which would be populated at different levels over a number of iterations, depending upon the synthesis approach used. In general, it is not created by a single top-down decomposition. A static functional hierarchy on its own does not represent how effectively the flows of

inputs and outputs are exchanged, and may need to be viewed alongside the other models below.

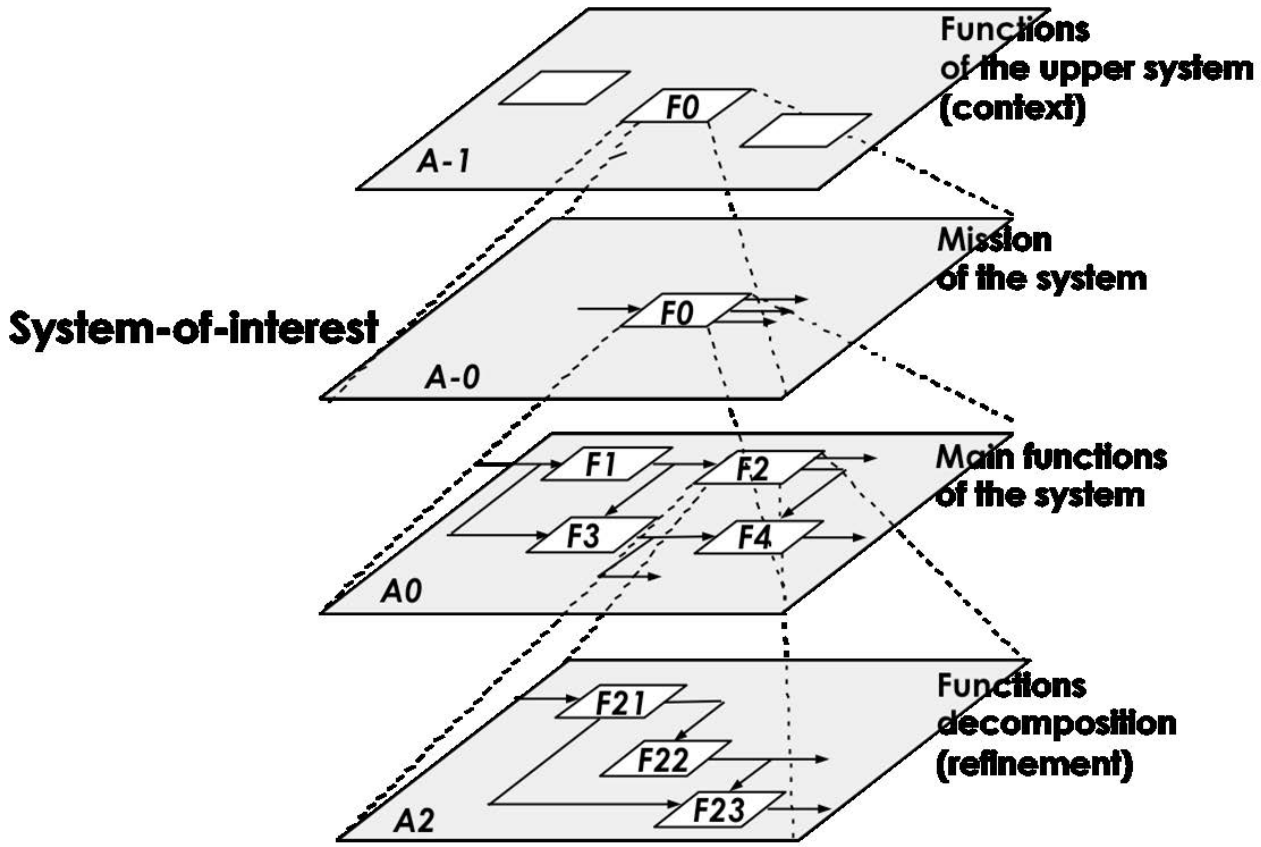

Figure 1. Decomposition of Functions (Faisandier 2012). Permission granted by Sinergy'Com. All other rights are reserved by the copyright owner.

Behavioral Architecture Model

A behavioral architecture model is an arrangement of functions and their sub-functions as well as interfaces (inputs and outputs) that defines the execution sequencing, conditions for control or data-flow, and performance level necessary to satisfy the system requirements (ISO/IEC 26702:2007). A behavioral architecture model can be described as a set of inter-related scenarios of functions and/or operational modes.

Control (Trigger) - A control flow is an element that activates a function as a condition of its execution. The state of this element, or the condition it represents, activates or deactivates the function (or elements thereof). A control flow can be a signal or an event, such as a switch being moved to the *on* position, an alarm, a trigger, a temperature variation, or the push of a key on a keyboard.

Scenario (of Functions) - A scenario of functions is a chain of functions that are performed as a sequence and synchronized by a set of control flows to work to achieve a global transformation of inputs into outputs, as seen in the figures below. A scenario of functions expresses the dynamic of an upper level function. A behavioral architecture is developed by considering both scenarios for each level of the functional hierarchy and for each level of the system hierarchy. When representing scenarios of functions and behavioral architecture models, it is appropriate to use diagrams as modeling techniques, such as functional flow block diagrams (FFBD) (Oliver, Kelliher, and Keegan 1997) or activity diagrams, developed with SysML (OMG 2010). Figures 2 and 3 provide examples of these diagrams.

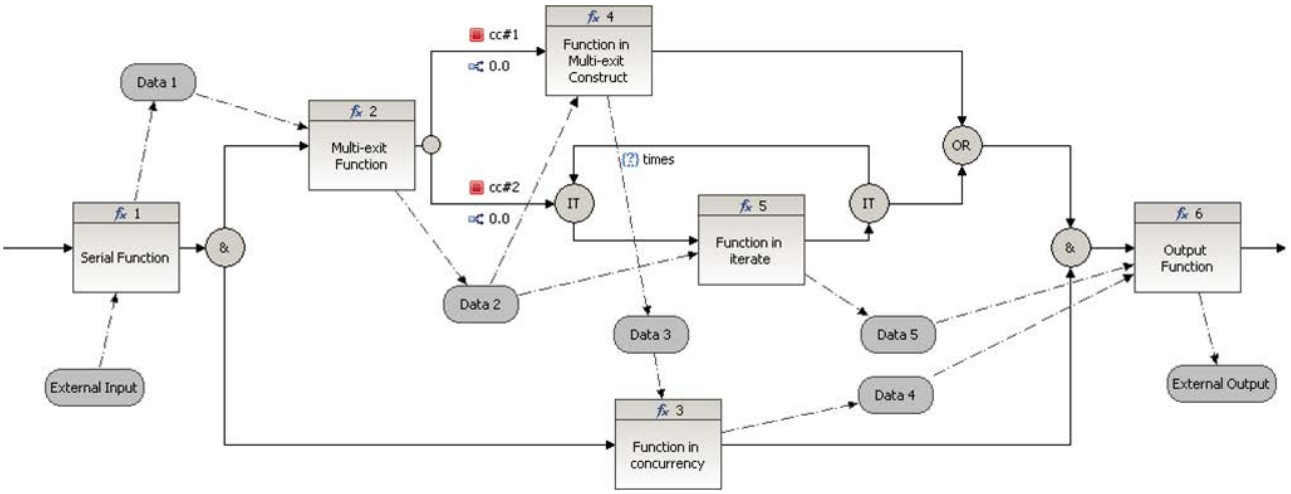

Figure 2. Illustration of a Scenario (eFFBD). (SEBoK Original)

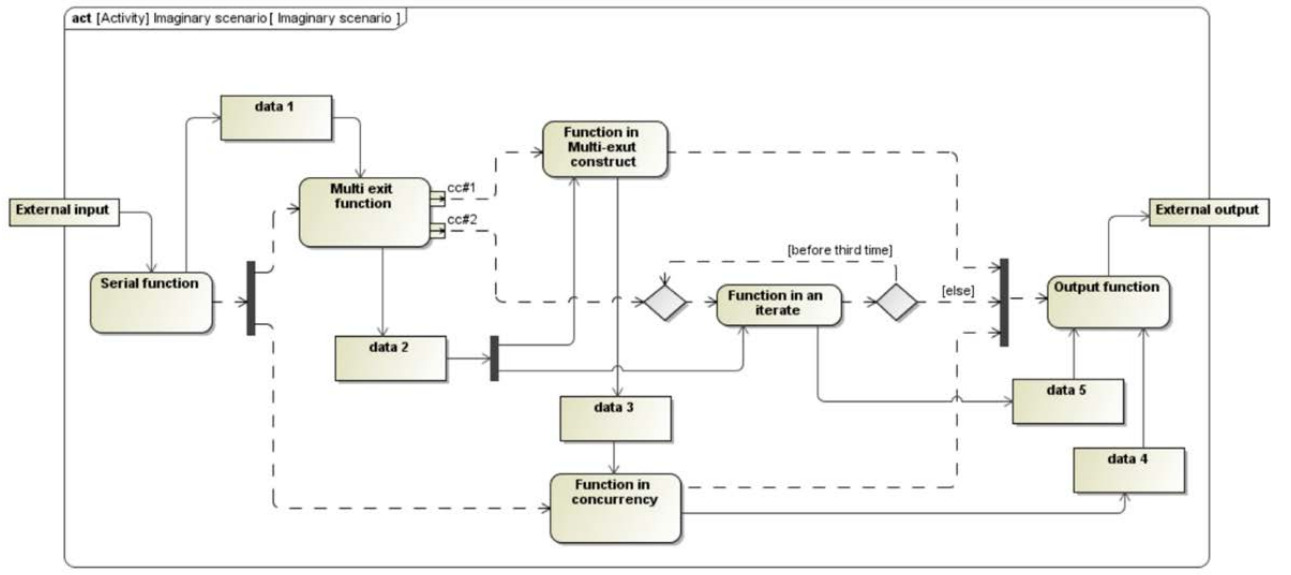

Figure 3. Illustration of a Scenario (Activity Diagram). (SEBoK Original)

Operational Mode - A scenario of functions can be viewed by abstracting the transformation of inputs into outputs of each function and focusing on the active or non-active state of the function and its controls. This view is called a *scenario of modes*, which is a chain of modes performed as a sequence of transitions between the various modes of the system. The transition from one mode to another is triggered by the arrival of a control flow (event/trigger). An action (function) can be generated within a transition between two modes following the arrival of an event or a trigger, as demonstrated in Figure 4 below.

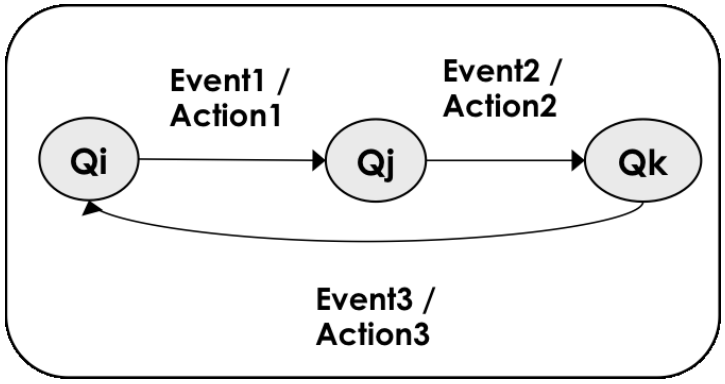

Figure 4. Scenario of Operational Modes (Faisandier 2012). Permission granted by Sinergy'Com. All other rights are reserved by the copyright owner.

Behavioral Patterns - When defining scenarios or behavioral architecture models, architects may opt to recognize and use known models to represent the expected transformations and behaviors. Patterns are generic basic models that may be more or less sophisticated depending on the complexity of the treatment (Gamma, Helm, Johnson, and Vlissides 1995). A pattern can be represented with different notations. Behavioral patterns are classified into several categories, which can be seen in the following examples (see also SEBoK Part 2: Patterns of Systems Thinking):

- Basic patterns or constructs linking functions - such as sequence, iteration, selection, concurrence, multiple exits, loops with an exit, and replication.
- Complex patterns - such as monitoring a treatment, exchanging a message, man machine interfaces, modes monitoring, real-time monitoring of processes, queue management, and continuous monitoring with supervision.
- Failure detection, identification, and recovery (FDIR) patterns - such as passive redundancies, active redundancies, semi-active redundancies, and treatments with reduced performance.

Temporal Architecture Model

A temporal architecture model is a classification of the functions of a system that is derived according to the frequency level of execution. Temporal architecture models include the definition of synchronous and asynchronous aspects of functions. The decision monitoring that occurs inside a system follows the same temporal classification because the decisions are related to the monitoring of functions.

Temporal and Decisional Hierarchy Concept - Not every function of a system is performed at the same frequency. The frequencies change depending on the time and the manner in which the functions are started and executed. One must therefore consider several classes of performance. There are synchronous functions that are executed cyclically and asynchronous functions that are executed following the occurrence of an event or trigger.

To be more specific, *real-time* systems and *command-control* systems combine cyclical operations (synchronous) and factual aspects (asynchronous). Cyclical operations consist of sharing the execution of functions according to frequencies, which depend on either the constraints of capture or dispatching the input/output and control flows. Two types of asynchronous events can be distinguished:

1. Disturbances on High Frequencies (bottom of figure 5) - Decisions that are made at either the level they occur or one level above. The goal is to deter disturbances from affecting the low frequencies so that the system continues to achieve its mission objectives. This is the way to introduce exception operations, with the typical example relating to operations concerns, breakdowns, or failures.
2. Changes on Low Frequencies (top of figure 5) - Decisions pertaining to changes that are made at the upper levels. The ultimate goal is to transmit them toward bottom levels to implement the modifications. A typical example relates to operator actions, maintenance operations, etc.

Process Approach

Purpose

The purpose of the Logical Architecture Model Development is to define, select, and synthesize a system's logical architecture model to provide a framework against which to verify that a future system will satisfy its system requirements in all operational scenarios, within which trade-offs between system requirements can be explored in developing such systems.

Generic inputs to the process include system requirements, generic architecture patterns that architects identify and use to answer requirements, outcomes from system analysis processes, and feedback from system verification and validation processes. Depending on the Life Cycle Model that is chosen, there will be iterations through which these inputs and outputs, and the relationships between them evolve and change throughout the process (see also Applying Life Cycle Processes).

Generic outputs from the process are either a single logical architecture model or a set of candidate logical architecture models together with the selected independent logical architecture model and a rationale for its selection. They include, at minimum, views and models. These involve functional, behavioral and temporal views, a traceability matrix between logical architecture model elements and system requirements.

Activities of the Process

Major activities and tasks performed during this process include the following:

- Identify and analyze functional and behavioral elements:
  - Identify functions, input-output flows, operational modes, transition of modes, and operational scenarios from system requirements by analyzing the functional, interface, and operational requirements.
  - Define necessary inputs and controls (energy, material, and data flows) to each function and outputs that result in the deduction of the necessary functions to use, transform, move, and generate the input-output flows.
- Assign system requirements to functional and behavioral elements:
  - Formally characterize functions expressions and their attributes through the assignment of performance, effectiveness, and constraints requirements. In particular, study the temporal aspects from requirements to assign duration, response time, and frequency to functions.
  - Formally characterize the input, output, and control flows expressions and their attributes through assignment of interface, effectiveness, operational, temporal and constraints requirements.
  - Establish traceability between system requirements and these functional and behavioral elements.
- Define candidate logical architecture models for each candidate:
  - Analyze operational modes as stated in the system requirements (if any) and/or use previously defined elements to model sequences of operational modes and the transition of modes. Eventually decompose the modes into sub-modes and then establish for each operational mode one or several scenarios of functions recognizing and/or using relevant generic behavioral patterns.
  - Integrate these scenarios of functions in order to get a behavioral architecture model of the system (a complete picture of the dynamic behavior).
  - Decompose previously defined logical elements as necessary to look towards implementation.
  - Assign and incorporate temporal constraints to previously defined logical elements, such as the period of time, duration, frequency, response-time, timeout, stop conditions, etc.
  - Define several levels of execution frequency for functions that correspond to levels of decision, in order to monitor system operations, prioritize processing on this time basis, and share out functions among those execution frequency levels to get a temporal architecture model.
  - Perform functional failure modes and effects analysis and update the logical architecture elements as necessary.
  - Execute the models with simulators (when possible) and tune these models to obtain the expected characteristics.
- Synthesize the selected independent logical architecture model:
  - Select the logical architecture by assessing the candidate logical architecture models against assessment criteria (related to system requirements) and compare them, using the system analysis process to perform assessments and decision management process for the selection (see the System Analysis and Decision Management topics). This selected logical architecture model is called *independent logical architecture model* because, as much as possible, it is independent of implementation decisions.
  - Identify and define derived logical architecture model elements created for the necessity of design and corresponding with the derived system requirements. Assign these requirements to the appropriate system (current studied system or external systems).
  - Verify and validate the selected logical architecture models (using as executable models as possible), make corrections as necessary, and establish traceability between system requirements and logical architecture model elements.
- Feedback logical architecture model development and system requirements. This activity is performed after the physical architecture model development process:

- Model the *allocated logical architecture* to systems and system elements, if such a representation is possible, and add any functional, behavioral, and temporal elements as needed to synchronize functions and treatments.
- Define or consolidate derived logical and physical elements induced by the selected logical and physical architecture models. Define the corresponding derived requirements and allocate them to appropriate logical and physical architectures elements. Incorporate these derived requirements into the requirements baselines of impacted systems.

Artifacts, Methods and Modeling Techniques

Logical architecture descriptions use modeling techniques that are grouped under the following types of models. Several methods have been developed to support these types of models (some are executable models):

- Functional Models – These include models such as the structured analysis design technique (SADT/IDEF0), system analysis & real time (SA-RT), enhanced Functional Flow Block Diagrams (eFFBD), and the function analysis system technique (FAST).
- Semantic Models- These include models such as entities-relationships diagrams, class diagrams, and data flow diagrams.
- Dynamic Models – These include such models as state-transition diagrams, state-charts, eFFBDs, state machine diagrams (SysML), activity diagrams (SysML) (OMG 2010), and petri nets.

Depending on the type of domain (e.g. defense, enterprise), architecture frameworks provide descriptions that can help to represent additional aspects/views of architectures - see the section 'Enterprise Architecture Frameworks & Methodologies' in Enterprise Systems Engineering Key Concepts. See also practical means for using general templates related to ISO/IEC/IEEE 42010 (ISO 2011).

Practical Considerations

As stated above, the purpose of the logical architecture model is to provide a description of what a system must be able to do to satisfy the stated need. This should help to ensure that the needs and/or concerns of all stakeholders are addressed by any solution, and that innovative solutions, as well as those based on current solution technologies, can be considered. In practice it is human nature for problem stakeholders to push their own agendas and for solution architects or designers to offer their familiar solutions. If a logical architecture model is not properly enforced with the chosen life cycle, it is easy for both problem and solution stakeholders to ignore it and revert to their own biases (see Part 5: Enabling Systems Engineering). This is exacerbated if the logical architecture model becomes an end in its own right or disconnected from the main lifecycle activities. This can occur either through the use of abstract language or notations, levels of detail, time taken, or an overly complex final architecture that does not match the purpose for which it was created. If the language, scope, and timeliness of the architecture are not matched to the problem stakeholder or solution providers, it is easier for them to overlook it. Key pitfalls and good practices which can help to avoid problems related to logical architecture models are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in developing logical architecture are provided in Table 1.

Table 1. Pitfalls with Logical Architecture Development. (SEBoK Original)

Pitfall	Description
Problem Relevance	The logical architecture model should relate back to the operational scenarios produced by mission analysis.
Inputs for Architecture Model	The major input for architecture definition activity involves the set of system requirements and the instances in which they do not address the right level of architecture. The consequence is that the architect allows the requirements to fall to the side and invents a solution with what he or she understands through the input.
Decomposition Too Deep	A common mistake made by many beginners in architecture consists of decomposing the functions too deeply or having too many functions and input/output flows in scenarios or in the functional architecture model of the current system block.
Not Considering Inputs and Outputs Together with Functions	A common mistake is to consider only the actions supported by functions and decomposing them, while forgetting the inputs and the outputs or considering them too late. Inputs and outputs are integral parts of a function.
Considering Static Decomposition of Functions Only	Static function decomposition is the smallest functional architecture model task and answers the basic question, "How is this done?" The purpose of the static decomposition is to facilitate the management of or navigation through the list of functions. The static decomposition should be established only when scenarios have been created and the logical architecture is close to complete.
Mixing Governance, Management, and Operation	Governance (strategic monitoring), management (tactical monitoring), and basic operations are often mixed in complex systems. Logical architecture model should deal with behavioral architecture model as well as with temporal architecture model.

Proven Practices

Some proven practices gathered from the references are provided in Table 2.

Table 2. Proven Practices with Logical Architecture Development. (SEBoK Original)

Practice	Description
Constitute Scenarios of Functions	Before constituting a decomposition tree of functions, one must model the behavior of the system, establish scenarios of functions, and decompose functions as scenarios of sub-functions.
Analysis and Synthesis Cycles	When facing a system that contains a large number of functions, one should attempt to synthesize functions into higher abstraction levels of functions with the assistance of criteria. Do not perform analysis only; instead, conduct small cycles of analysis (decomposition) and synthesis. The technique of using scenarios includes this design practice.
Alternate Functional and Behavioral Views	A function (action verb; e.g. "to move") and its state of execution/operational mode (e.g. "moving") are two similar and complimentary views. Utilize this to consider a behavioral view of the system that allows for the transition from one operational mode to another.
The Order to Create a Scenario of Functions	When creating a scenario of functions, it is more efficient to first establish the (control) flow of functions, then to add input and output flows, and finally to add triggers or signals for synchronization.

Physical Architecture

- Lead Authors:
- Alan Faisandier and Rick Adcock

-

Physical Architecture Model Development may be used as a task of the activity "Develop candidate architectures models and views," or a sub-process of the System Architecture Design Definition process. Its purpose is to elaborate models and views of a physical, concrete solution that accommodates the logical architecture model and satisfies and trades-off system requirements. Once a logical architecture model is defined (see Logical Architecture Model Development), concrete physical elements have to be identified that can support functional, behavioral, and temporal features as well as the expected properties of the system deduced from non-functional system requirements (e.g. constraint of replacement of obsolescence, and/or continued product support).

A physical architecture model is an arrangement of physical elements, (system elements and physical interfaces) that provides the solution for a product, service, or enterprise. It is intended to satisfy logical architecture elements and system requirements ISO/IEC/IEEE 26702 (ISO 2007). It is implementable through technological system elements. System requirements are allocated to both the logical and physical architectures. The resulting system architecture is assessed with system analysis and when completed becomes the basis for system realization.

In some cases, particularly when multiple systems are to be defined to a common physical architecture model, one of the drivers for the physical architecture model may be interface standards; these physical interfaces may well be one of the most important concerns for these systems. It is quite possible that such interface standards are mandated at a high level in the system requirements. On the other hand, it is equally possible for standards to be derived during physical architecture model development and these can be critical enablers for desirable engineering outcomes, such as: families of systems, technology insertion, interoperability and “open systems”. For example, today’s video, hi-fi, and computer systems have all benefited from adoption of interface standards. Other examples exist in most fields of engineering from nuts and bolts, plumbing, electrical installations, rail gauges, TCP/IP, IT systems and software to modular defense and space systems.

Note: The term *Physical Architecture* is a contraction of the expression *Physical View of the System Architecture*.

Concepts and Principles

System Element, Physical Interface, and Physical Architecture Model

A system element is a discrete part of a system that can be implemented to fulfill design properties. A system element can be hardware, software, data, humans, processes (e.g., processes that provide a service to users), procedures (e.g., operator instructions), facilities, materials, and naturally occurring entities (e.g., water, organisms, and minerals), or any combination of these ISO/IEC/IEEE 15288 (ISO 2023). A physical interface binds two system elements together; this is similar to a link or a connector. Table 1 provides some examples of system elements and physical interfaces.

Table 1. Types of System Elements and Physical Interfaces. (SEBoK Original)

Element	Product System	Service System	Enterprise System
System Element	• Hardware Parts (mechanics, electronics, electrical, plastic, chemical, etc.) • Operator Roles • Software Pieces	• Processes, Data Bases, Procedures, etc. • Operator Roles • Software Applications	• Corporate, Direction, Division, Department, Project, Technical Team, Leader, etc. • IT Components
Physical Interface	* Hardware Parts, Protocols, Procedures, etc.	* Protocols, Documents, etc.	* Protocols, Procedures, Documents, etc.

A complex system composed of thousands of physical and/or intangible parts may be structured in several layers of systems and system elements. The number of elements in a level of the structure of one system is limited to only a few, in order to facilitate managing the system definition; a common guideline is *five plus or minus two* elements (see illustration in Figure 1).

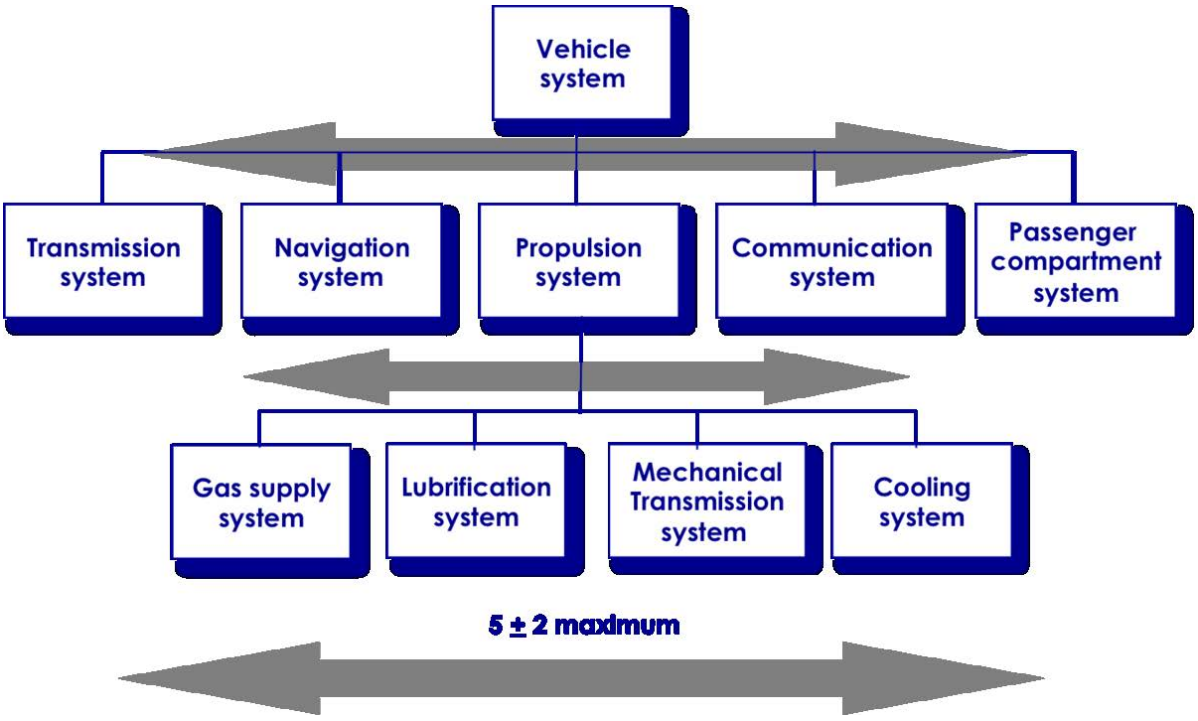

Figure 1. Layers of Systems and System Elements (Faisandier 2012). Permission granted by Sinergy'Com. All other rights are reserved by the copyright owner.

A physical architecture model is built from systems, system elements, and all necessary physical interfaces between these elements, as well as from external elements (neighboring or enabling systems and/or system elements in the considered layer and concerned elements in the context of the global system-of-interest) - see illustration in Figure 2.

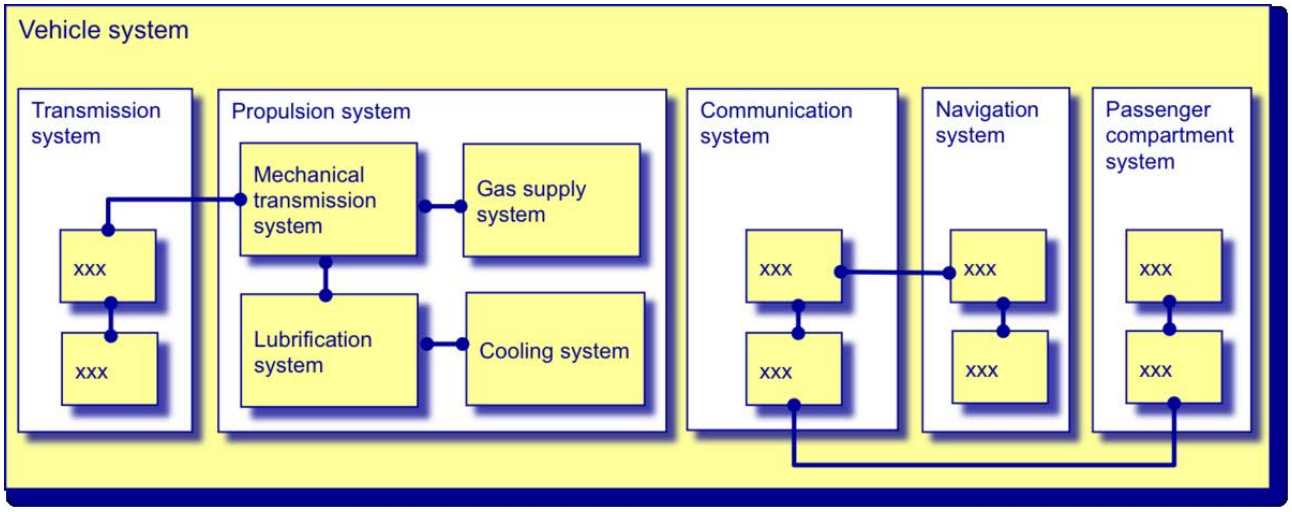

Figure 2. Physical Architecture Model Representation (Faisandier 2012). Permission granted by Sinergy'Com. All other rights are reserved by the copyright owner.

Design Property

A design property is a property that is obtained during system architecture and created through the assignment of non-functional requirements, estimates, analyses, calculations, simulations of a specific aspect, or through the definition of an existing element associated with a system element, a physical interface, and/or a physical architecture. If the defined element complies with a requirement, the design property will relate to (or may equal) the requirement. Otherwise, one has to identify any discrepancy that could modify the requirement or design property and detect any deviations.

Stakeholders have concerns that correspond to the expected behavior of a system within operational, environmental, and/or physical constraints as well as to more general life cycle constraints. Stakeholder needs and requirements and system requirements express these concerns as expected capabilities from the system (e.g., usability, interoperability, security, expandability, environment suitability, etc.). Architects and/or designers identify these capabilities from requirements and deduce corresponding quantitative or qualitative design properties to properly equip their physical architecture model (e.g., reliability, availability, maintainability, modularity, robustness, operability, climatic environment resistance, dimensions limits, etc.). For further discussion on how some of these properties may be included in architecture and design, please see the article Systems Engineering and Quality Attributes in the Related Disciplines Part.

Allocation of Logical Elements to Physical Elements and Partitioning

Developing a candidate physical architecture model for a system consists of first identifying the system elements that can perform functions of the logical architecture model as well as identifying the interfaces capable of carrying out the input-output flows and control flows. When identifying potential elements, a systems engineer needs to allocate design properties within the logical architecture; these properties are deduced from the system requirements. Partitioning and allocation are activities to decompose, gather, or separate functions in order to facilitate the identification of feasible system elements that support these functions. Either they exist and can be reused or re-purposed, or they can be developed and technically implemented.

Partitioning and allocation use criteria to find potential affinities between functions. Systems engineers use system requirements and/or design properties as criteria to assess and select candidate system elements and partitions of functions, such as similar transformations within the same technology, similar levels of efficiency, exchange of the same type of input-output flows (information, energy, and materials), centralized or distributed controls, execution

with close frequency level, dependability conditions, environment resistance level, and other enterprise constraints.

A concurrent engineering approach is necessary when several different sets of technologies, knowledge, and skills are necessary to establish a candidate physical architecture model. This is particularly true during the partition and allocation of functions to various system elements, in which the systems engineer must account for compatibility issues and emergent properties. (See SEBoK Part 2: Synthesizing Possible Solutions for a discussion of possible approaches.)

Developing Candidate Physical Architecture Models

The goal of physical architecture model development activities is to provide the best possible physical architecture model made of suitable systems, technological system elements, and physical interfaces (i.e., the architecture that answers, at best, all system requirements, depending on agreed limits or margins of each requirement). The best way to do this is to produce several candidate physical architecture models, assess and compare them, and then select the most suitable one.

A candidate physical architecture model is elaborated according to affinity criteria in order to build a set of system elements (i.e., separate, gather, connect, and disconnect the network of system elements and their physical interfaces). These criteria are the same as those used for partitioning and allocating functions to system elements. The physical architecture model development may be focused in different ways, for example, it may address:

- Reduction in the number of physical interfaces
- System elements that can be tested separately
- Compatible technology
- Measures of the proximity of elements in space
- Ease of handling (weight, volume, and transportation facilities)
- Optimization of resources shared between elements
- Modularity (i.e. elements have low interdependence)
- Resilience (i.e. elements which are highly reliable, maintainable or replaceable)

Evaluating and Selecting the Preferred Candidate

Viable physical architecture models enable all required functions or capabilities specified in the logical architecture model to be realized. Architecture and design activity includes evaluation to obtain a balance among design properties, costs, risks, etc. Generally, the physical architecture model of a system is determined more strongly by non-functional requirements (e.g., performance, safety, security, environmental conditions, constraints, etc.) than by functions. There may be many (physical) ways to establish functions but fewer ways of satisfying non-functional requirements. The preferred physical architecture model represents the selection of system elements, their physical relationships, and interfaces. Typically, this physical architecture will still leave further systems engineering to be undertaken to achieve a fully optimized system after any remaining trade-offs are made and algorithms and parameters of the system are finalized. Certain analyses (efficiency, dependability, cost, risks, etc.) are required to get sufficient data that characterize the global behavior and structure of the candidate architectures in regard to system requirements; this is often broadly referred to as system analysis. Other analyses and assessments require knowledge and skills from the different involved technologies and specialties (mechanics, electronics, software, thermodynamics, electro-magnetic compatibility, safety, security etc.). They are performed through corresponding specialist analysis of the system.

Legacy Systems and Systems of Systems

Few systems come into existence or operate without interacting with others in a system context. These interactions may be with other operational systems, or maintenance and support systems, which in turn may be legacy (already in use) or future legacy (under development and likely to operate with the system of interest in the future).

The best chosen approach will be dependent on the strength of interactions between the system-of-interest (SoI) and its wider context. While these interactions are small, they may be accounted for by defining a set of static external interface requirements (for example, technical standards) with which the system must comply, by including these as constraints in the system requirements and ensuring compliance through design assurance.

Where the interactions are more intense (for example, where continuous information is to be exchanged with other systems), these will have to be recognized as part of a system of systems context and will instead be considered as part of an enterprise systems engineering approach.

Another important consideration may be the sharing of technology or system elements between the SoI and other systems, often as part of a family of systems (many examples occur in automotive and aerospace industries) or the re-use of system elements from existing legacy. Here a degree of top-down or middle-out design work will be necessary to ensure the system of interest embodies the required system elements, while conforming as far as possible to the stakeholder and system requirements, with any compromises being understood and managed.

If a System-of-Interest is intended to be used in one or more service systems or system of systems configurations, this will affect its physical architecture model. One of the features of these SoS is the late binding of component systems in use. Such component systems must be architected with open or configurable interfaces, must have clearly defined functions packaged in such a way as to be relevant to the SoS using them, and must include some method by which they can be identified and included in the SoS when needed.

Both service systems and SoS will be defined by a high-level physical architecture model, which will be utilized to define the relevant SoS relationships, interfaces, and constraints that should be included in System Concept Definition. The results will be embedded in the stakeholder and system requirements and handled through interface agreements and across-project communication during development, realization, and use.

See SEBoK Part 4: Applications of Systems Engineering for more information on special considerations for architecting SoS.

Process Approach

Purpose

The purpose of the Physical Architecture Model Development is to define, select, and synthesize a system physical architecture model which can support the logical architecture model. A physical architecture model will have specific properties to address stakeholder concerns or environmental issues and to satisfy system requirements.

Because of the evolution of the context of use or technological possibilities, the physical architecture which is composed of system elements is supposed to evolve along the life cycle of the system in order for it to continue to perform its mission within the limits of its required effectiveness. Depending on whether or not evolution impacts logical architecture model elements, allocations to system elements may change. A physical architecture model is equipped with specific design properties to continuously challenge the evolution.

Generic inputs include the selected logical architecture model, system requirements, generic patterns and properties that architects identify and utilize to answer requirements, outcomes from system analysis, and feedback from system verification and system validation.

Generic outputs are the selected physical architecture model, allocation matrix of functional elements to physical elements, traceability matrix with system requirements, stakeholder requirements of each system and system element composing the physical architecture model, and rejected solutions.

Activities of the Process

Major activities and tasks to be performed during this process include the following:

- Partition and allocate functional elements to system elements:
  - Search for system elements or technologies able to perform functions and physical interfaces to carry input-output and control flows. Ensure system elements exist or can be engineered. Assess each potential system element using criteria deduced from design properties (themselves deduced from non-functional system requirements).
  - Partition functional elements (functions, scenarios, input-outputs, triggers, etc.) using the given criteria and allocate partitioned sets to system elements (using the same criteria).
  - When it is impossible to identify a system element that corresponds to a partitioned functional set, decompose the function until the identification of implementable system elements is possible.
  - Check the compatibility of technologies and the compatibility of interfaces between selected system elements.
- Constitute candidate physical architecture models.
  - Because partitioned sets of functions can be numerous, there are generally too many system elements. For defining controllable architectures, system elements have to be grouped into higher-level system elements known as system element groups, often called sub-systems in industry.
  - Constitute several different system element groups corresponding to different combinations of elementary system elements. One set of system element groups plus one or several non-decomposable system elements forms a candidate physical architecture model of the considered system.
  - Represent (using patterns) the physical architecture model of each system element group connecting its system elements with physical interfaces that carry input-output flows and triggers. Add physical interfaces as needed; in particular, add interfaces with external elements to the system element group.
  - Represent the synthesized physical architecture of the considered system built from system element groups, non-decomposable systems, and physical interfaces inherited from the physical architecture model of system element groups.
  - Enhance the physical architecture model with design properties such as modularity, evolution capability, adaptability to different environments, robustness, scalability, resistance to environmental conditions, etc.
  - If possible, use executable architecture prototypes (e.g., hardware-software (HW-SW)-in-the-loop prototypes) for identifying potential deficiencies and correct the architecture as needed.
- Assess physical architecture model candidates and select the most suitable one:
  - Use the system analysis process to perform assessments (see the System Analysis topic).
  - Use the Decision Management process to support the trades and selection of the preferred alternative (see the Decision Management topic).
- Synthesize the selected physical architecture model:
  - Formalize physical elements and properties. Verify that system requirements are satisfied and that the solution is realistic.
  - Identify the derived physical and functional elements created for the necessity of architecture and design and the corresponding system requirements.
  - Establish traceability between system requirements and physical elements as well as allocate matrices between functional and physical elements.

Artifacts, Methods and Modeling Techniques

Physical architecture descriptions use modeling techniques to create and represent physical architectures. Some common physical models include structural blocks, mass, layout and other models. Modeling techniques may be:

- Physical block diagrams (PBD)
- SysML block definition diagrams (BDD)
- Internal block diagrams (IBD) (OMG 2010)
- Executable architecture prototyping
- Etc.

Depending on the type of domain for which it is to be used (defense, enterprise, etc.), architecture frameworks may provide descriptions that can help to trade-off candidate architectures. Please see section 'Enterprise Architecture Frameworks & Methodologies' in Enterprise Systems Engineering Key Concepts.

Practical Considerations

Key pitfalls and good practices related to physical architecture development are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in performing physical architecture model development are provided in Table 3.

Table 3. Pitfalls with Physical Architecture Development. (SEBoK Original)

Pitfall	Description
Too Many Levels in a Single System Block	The current system block includes too many levels of decomposition. The right practice is that the physical architecture model of a system block is composed of one single level of systems and/or system elements.
No Logical Architecture Model	The developers perform a direct passage from system requirements to a physical architecture model without establishing a logical architecture model; this is a common wrong practice that mainly takes place when dealing with repeating systems and products because the functions are already known. The issue is that a function is always associated with input-output flows defined in a specific domain set. If the domain set changes, the performance of the function can become invalid.
Direct Allocation on Technologies	At a high level of abstraction of multidisciplinary systems, directly allocating the functions onto technologies of the lowest level of abstraction, such as hardware or software, does not reflect a system comprehension. The right practice is to consider criteria to decompose the architecture into the appropriate number of levels, alternating logical and physical before reaching the technology level (the last level of the system).

Proven Practices

Some proven practices gathered from the references are provided in Table 4.

Table 4. Proven Practices with Physical Architecture Development. (SEBoK Original)

Practice	Description
Modularity	Restrict the number of interactions between the system elements and consider the modularity principle (maximum of consistency inside the system element, minimum of physical interfaces with outside) as the right way for architecting systems.
Focus on Interfaces	Focusing on interfaces rather than on system elements is another key element of a successful architecture and design for abstract levels of systems.

System Detailed Design Definition

- Lead Authors:
- Alan Faisandier and Rick Adcock

-

The purpose of the System Design is to supplement the system architecture by providing information and data useful and necessary for implementation of the system elements. Design definition is the process of developing, expressing, documenting, and communicating the realization of the architecture of the system through a complete set of design characteristics described in a form suitable for implementation.

Concepts and Principles

Design Notion

In industrial practices, the term *design* is often used to mean both architecture and design. In the recent past, professionals used the term *design* when they dealt with simpler technological products - ones that do not include several different and interconnected technological components such as hardware, software, operators, services, etc. In the development of new multi-technology products and services, professionals have recognized the usefulness of the notion of *system* in dealing with complexity (interconnections level, multi-techno, emergence, etc.).

It was due to complexity that structuring the elements that comprise a system became necessary. This structure explains the functional, behavioral, temporal, physical, and other aspects of a system as described in System Architecture Design Definition. Practitioners found the term *structure* inadequate to describe all these aspects of a system. The terms *architecture* and *architectural design* have been used for approximately 30 years, especially in software intensive systems and other domains, such as the space industry. The set of different types and interrelated structures can be understood as the architecture of the system.

The trend today is to consider system architecture and system design as different and separate sets of activities, but concurrent and strongly intertwined.

System design includes activities to conceive a set of system elements that answers a specific, intended purpose, using principles and concepts; it includes assessments and decisions to select system elements that compose the system, fit the architecture of the system, and comply with traded-off system requirements. It is the complete set of detailed models, properties, and/or characteristics described into a form suitable for implementation.

Design Characteristics and Design Enablers

Every technological domain or discipline owns its peculiar laws, rules, theories, and enablers concerning transformational, structural, behavioral, and temporal properties of its composing parts of materials, energy, or information. These specific parts and/or their compositions are described with typical design characteristics and enablers. These allow achieving the implementation of every system element through various transformations and exchanges required by design characteristics (e.g., operability level, reliability rate, speed, safeguard level) that have been assigned during the system architecture definition process.

The design definition provides the description of the design characteristics and design enablers necessary for implementation. Design characteristics include dimensions, shapes, materials, and data processing structures. Design

enablers include formal expressions or equations, drawings, diagrams, tables of metrics with their values and margins, patterns, algorithms, and heuristics.

- Examples of generic design characteristics in mechanics of solids: shape, geometrical pattern, dimension, volume, surface, curves, resistance to forces, distribution of forces, weight, velocity of motion, temporal persistence
- Examples of generic design characteristics in software: distribution of processing, data structures, data persistence, procedural abstraction, data abstraction, control abstraction, encapsulation, creational patterns (e.g., builder, factory, prototype, singleton), and structural patterns (e.g., adapter, bridge, composite, decorator, proxy)

Relation with System Architecture

System design is intended to be the link between the system architecture (at whatever point this milestone is defined in the specific application of the systems engineering process) and the implementation of technological system elements that compose the physical architecture model of the system.

Design definition is driven by specified requirements, the system architecture, and more detailed analysis of performance and feasibility. It addresses the implementation technologies and their assimilation. Design provides the “how-” or “implement-to” level of the definition.

Design concerns every system element composed of implementation technologies, such as mechanics, electronics, software, chemistry, human operations and services for which specific engineering processes are needed. System design provides feedback to the parent system architecture to consolidate or confirm the allocation and partitioning of architectural characteristics and design properties to system elements.

Design Descriptor

A design descriptor is the set of generic design characteristics and of their possible values. If similar, but not exact system elements exist, it is possible to analyze these in order to identify their basic characteristics. Variations of the possible values of each characteristic determine potential candidate system elements.

Holistic Design

Holistic design is an approach that considers the system being designed as an interconnected whole, which is also part of something larger. Holistic concepts can be applied to the system as a whole along with the system in its context (e.g., the enterprise or mission in which the system participates), as well as the design of mechanical devices, the layout of spaces, and so forth. This approach often incorporates concerns about the environment, considering how the design will impact the environment and attempting to reduce environmental impact. Holistic design is about more than merely trying to meet the system requirements.

Process Approach

Purpose

The purpose of the System Design process is to provide sufficient detailed data and information about the system and its system elements to enable the implementation consistent with architectural entities as defined in models and views of the system architecture (ISO/IEC/IEEE 15288 [ISO 2015]).

Generic inputs include architecture description of the parent system and system element requirements.

Generic outputs are the description of the design characteristics and design enablers necessary for implementation.

Activities of the Process

Major activities and tasks to be performed during this process include the following:

1. Initialize design definition

- Plan for technology management for the whole system. Identify the technologies (mechanics, electricity, electronics, software, biology, operators, etc.) that would compose and implement the system elements and their physical interfaces.
- Determine which technologies and system elements have a risk to become obsolete or evolve during the operation stage of the system. Plan for their potential replacement.
- Identify types of design characteristics or properties for each technology of each system element.
- Periodically assess design characteristics and adjust as the system evolves.
- Document the design definition strategy, including the need for and requirements of any enabling systems, products, or services to perform the design.

2. Establish design characteristics and design enablers related to each system element

- Perform, consolidate or detail system requirements allocation to system elements for all requirements and system elements not fully addressed in the System Architecture process (normally, every system requirement would have been transformed into architectural entities and architectural characteristics within the System Architecture process, which are then allocated to system elements through direct assignment or some partitioning).
- Define the design characteristics relating to the architectural characteristics and check that they are implementable. Use design enablers, such as models (physical and analytical), design heuristics, etc. If the design characteristics are not feasible, then assess other design alternatives or implementation option, or perform trades of other system elements definition.
- Define the interfaces that were not defined by the System Architecture process or that need to be refined as the design details evolve. This includes both internal interfaces between the system elements and the external interfaces with other systems.
- Record the design characteristics of each system element within the applicable artifacts (they depend on the design methods and techniques used).
- Provide rationale about selection of major implementation options and enablers.

3. Assess alternatives for obtaining system elements

- Identify existing implemented system elements (COTS/NDI, reused, or other non-developed system elements). Alternatives for new system elements to be developed may be studied.
- Assess design options for the system element, using selection criteria that are derived from the design characteristics.
- Select the most appropriate alternatives.
- If the decision is made to develop the system element, the rest of the design definition process and the implementation process are used. If the decision is to buy or reuse a system element, the acquisition process may be used to obtain the system element.

4. Manage the design

- Capture and maintain the rationale for all selections among alternatives and decisions for the design, architecture characteristics, design enablers, and sources of system elements.
- Assess and control the evolution of the design characteristics, including the alignment with the architecture.
- Establish and maintain traceability between design characteristics and architectural characteristics, and with requirements as necessary.
- Provide baseline information for configuration management.
- Maintain the design baseline and the design definition strategy.

Practical Considerations

Key pitfalls and proven practices related to system design are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in performing system design are provided in Table 1.

Pitfall	Description
Consider the design of each system element separately	This would be conducted using heterogeneous implementation of a given technology or between technologies within the system-of-interest. The design strategy for the complete system is defined to find synergies and/or commonalities that could help operation and maintenance of system elements.

Proven Practices

Some proven practices gathered from the references are provided in Table 2.

Practice	Description
Architecture and design mutual support	Discipline engineers perform the design definition of each system element; they provide strong support (knowledge and competencies) to systems engineers or architects in the evaluation and selection of candidate system architectures and system elements. Inversely, systems engineers, or architects, must provide feedback to discipline engineers to improve knowledge and know-how.

System Analysis

- Lead Authors:
- Alan Faisandier and Ray Madachy
- Contributing Author:
- Rick Adcock

-

System analysis allows developers to objectively carry out quantitative assessments of systems in order to select and/or update the most efficient system architecture and to generate derived engineering data. During engineering, assessments should be performed every time technical choices or decisions are made to determine compliance with system requirements.

System analysis provides a rigorous approach to technical decision-making. It is used to perform trade-off studies, and includes modeling and simulation, cost analysis, technical risks analysis, and effectiveness analysis.

Principles Governing System Analysis

One of the major tasks of a systems engineer is to evaluate the engineering data and artifacts created during the systems engineering (SE) process. The evaluations are at the center of system analysis, providing means and techniques:

- to define assessment criteria based on system requirements;
- to assess design properties of each candidate solution in comparison to these criteria;
- to score the candidate solutions globally and to justify the scores; and
- to decide on the appropriate solution(s).

The Analysis and Selection between Alternative Solutions article in the Systems Approach Applied to Engineered Systems knowledge area (KA) of Part 2 describes activities related to selecting between possible system solutions to an identified problem or opportunity. The following general principles of systems analysis are defined:

- Systems analysis is based on assessment criteria based upon a problem or opportunity system description.
  - These criteria will be based around an ideal system description, which assumes a hard system problem context can be defined.
  - Criteria must consider required system behavior and properties of the complete solution, in all possible wider system contexts and environments.

    - These must consider non-functional issues such as system safety, security, etc. (Please see Systems Engineering and Specialty Engineering for additional discussion on incorporating non-functional elements.)
    - This "ideal" system description may be supported by soft system descriptions, from which additional “soft” criteria may be defined. For example, a stakeholder preference for or against certain kinds of solutions, relevant social, political or cultural conventions to be considered, etc.
- The assessment criteria should include, at a minimum, the constraints on cost and time scales acceptable to stakeholders.
- Trade studies provide a mechanism for conducting analysis of alternative solutions.
    - A trade study should consider a set of assessment criteria, with appropriate awareness of the limitations and dependencies between individual criteria.
    - Trade studies need to deal with both objective and subjective criteria. Care must be taken to assess the sensitivity of the overall assessment to particular criteria.

Trade-Off Studies

In the context of the definition of a system, a trade-off study consists of comparing the characteristics of each system element and of each candidate system architecture to determine the solution that best globally balances the assessment criteria. The various characteristics analyzed are gathered in cost analysis, technical risks analysis, and effectiveness analysis (NASA 2007).

Guidance on the conduct of trade studies for all types of system context are characterized in the above principles and described in more detail in the Analysis and Selection between Alternative Solutions topic. Of particular interest to SE analysis are technical effectiveness, cost, and technical risk analysis.

Effectiveness Analysis

The effectiveness of an engineered system solution includes several essential characteristics that are generally gathered in the following list of analyses, including (but not limited to): performance, usability, dependability, manufacturing, maintenance or support, environment, etc. These analyses highlight candidate solutions under various aspects.

It is essential to establish a classification that limits the number of analyses to the really significant aspects, such as key performance parameters. The main difficulties of effectiveness analysis are to sort and select the right set of effectiveness aspects; for example, if the product is made for a single use, maintainability will not be a relevant criterion.

Cost Analysis

A cost analysis considers the full life cycle costs. A cost baseline can be adapted according to the project and the system. The global life cycle cost (LCC), or total ownership cost (TOC), may include exemplary labor and non-labor cost items such as those indicated in Table 1.

Table 1. Types of Costs. (SEBoK Original)

Type of Cost	Description and Examples
Development	Engineering, development tools (equipment and software), project management, test-benches, mock-ups and prototypes, training, etc.
Product manufacturing or service realization	Raw materials and supplies, spare parts and stock assets, necessary resources to operation (water, electricity power, etc.), risks and nuances, evacuation, treatment and storage of waste or rejections produced, expenses of structure (taxes, management, purchase, documentation, quality, cleaning, regulation, controls, etc.), packing and storage, documentation required.
Sales and after-sales	Expenses of structure (subsidiaries, stores, workshops, distribution, information acquisition, etc.), complaints and guarantees, etc.
Customer utilization	Taxes, installation (customer), resources necessary to the operation of the product (water, fuel, lubricants, etc.), financial risks and nuisances, etc.
Supply chain	Transportation and delivery.
Maintenance	Field services, preventive maintenance, regulation controls, spare parts and stocks, cost of guarantee, etc.
Disposal	Collection, dismantling, transportation, treatment, waste recycling, etc.

Methods for determining cost are described in the Project Planning topic.

Technical Risks Analysis

Every risk analysis concerning every domain is based on three factors:

1. Analysis of potential threats or undesired events and their probability of occurrence.
2. Analysis of the consequences of these threats or undesired events and their classification on a scale of gravity.
3. Mitigation to reduce the probabilities of threats and/or the levels of harmful effect to acceptable values.

The technical risks appear when the system cannot satisfy the system requirements any longer. The causes reside in the requirements and/or in the solution itself. They are expressed in the form of insufficient effectiveness and can have multiple causes: incorrect assessment of technological capabilities; over-estimation of the technical maturity of a system element; failure of parts; breakdowns; breakage, obsolescence of equipment, parts, or software, weakness from the supplier (non-compliant parts, delay for supply, etc.), human factors (insufficient training, wrong tunings, error handling, unsuited procedures, malice), etc.

Technical risks are not to be confused with project risks, even if the method to manage them is the same. Although technical risks may lead to project risks, technical risks address the system itself, not the process for its development. (See Risk Management for more details.)

Process Approach

Purpose and Principles of the Approach

The system analysis process is used to: (1) provide a rigorous basis for technical decision making, resolution of requirement conflicts, and assessment of alternative physical solutions (system elements and physical architectures); (2) determine progress in satisfying system requirements and derived requirements; (3) support risk management; and (4) ensure that decisions are made only after evaluating the cost, schedule, performance, and risk effects on the engineering or re-engineering of a system (ANSI/EIA 1998). This process is also called the decision analysis process by NASA (2007, 1-360) and is used to help evaluate technical issues, alternatives, and their uncertainties to support decision-making. (See Decision Management for more details.)

System analysis supports other system definition processes:

- Stakeholder needs definition and system requirements definition processes use system analysis to solve issues relating to conflicts among the set of requirements; in particular, those related to costs, technical risks, and effectiveness (performances, operational conditions, and constraints). System requirements subject to high risks, or those which would require different architectures, are discussed.
- The Logical Architecture Model Development and Physical Architecture Model Development processes use it to assess characteristics or design properties of candidate logical and physical architectures, providing arguments for selecting the most efficient one in terms of costs, technical risks, and effectiveness (e.g., performances, dependability, human factors, etc.).

Like any system definition process, the system analysis process is iterative. Each operation is carried out several times; each step improves the precision of analysis.

Activities of the Process

Major activities and tasks performed within this process include:

- Planning the trade-off studies:
  - Determine the number of candidate solutions to analyze, the methods and procedures to be used, the expected results (examples of objects to be selected: behavioral architecture/scenario, physical architecture, system element, etc.), and the justification items.
  - Schedule the analyses according to the availability of models, engineering data (system requirements, design properties), skilled personnel, and procedures.
- Define the selection criteria model:
  - Select the assessment criteria from non-functional requirements (performances, operational conditions, constraints, etc.), and/or from design properties.
  - Sort and order the assessment criteria.
  - Establish a scale of comparison for each assessment criterion and weigh every assessment criterion according to its level of relative importance with the others.
- Identify candidate solutions, related models, and data.
- Assess candidate solutions using previously defined methods or procedures:
  - Carry out cost analysis, technical risks analysis, and effectiveness analysis placing every candidate solution on every assessment criterion comparison scale.
  - Score every candidate solution as an assessment score.
- Provide results to the calling process: assessment criteria, comparison scales, solutions' scores, assessment selection, and possibly recommendations and related arguments.

Artifacts and Ontology Elements

This process may create several artifacts, such as:

- A selection criteria model (list, scales, weighing)
- Costs, risks, and effectiveness analysis reports
- Justification reports

This process handles the ontology elements of Table 2 within system analysis.

Table 2. Main Ontology Elements as Handled within System Analysis. (SEBoK Original)

Assessment Criterion	In the context of system analysis, an assessment criterion is a characteristic used to assess or compare system elements, physical interfaces, physical architectures, functional architectures/scenarios, or any engineering elements that can be compared.
	Identifier; name; description; relative weight; scalar weight
Assessment Selection	In the context of system analysis, an assessment selection is a technical management element based on an assessment score that justifies the selection of a system element, a physical interface, a physical architecture, or a functional architecture/scenario.
Assessment Score	In the context of system analysis, an assessment score is obtained assessing a system element, a physical interface, a physical architecture, a functional architecture/scenario using a set of assessment criteria.
	Identifier; name; description; value
Cost	In the context of systems engineering, a cost is an amount expressed in a given currency related to the value of a system element, a physical interface, and a physical architecture.
	Identifier; name; description; amount; type (development, production, utilization, maintenance, disposal); confidence interval; period of reference; estimation technique
Risk	An event having a probability of occurrence and consequences related to the system mission or on other characteristics. (Used for technical risk in engineering.). A risk is the combination of vulnerability and a danger or threat.
	Identifier; name description; status

Checking Correctness of System Analysis

The main items to be checked within system analysis in order to get validated arguments are:

- Relevance of the models and data in the context of use of the system,
- Relevance of assessment criteria related to the context of use of the system,
- Reproducibility of simulation results and of calculations,
- Precision level of comparisons' scales,
- Confidence of estimates, and
- Sensitivity of solutions' scores related to assessment criteria weights.

See Ring, Eisner, and Maier (2010) for additional perspective.

Methods and Modeling Techniques

- **General usage of models**: Various types of models can be used in the context of system analysis:
  - **Physical models** are scale models allowing simulation of physical phenomena. They are specific to each discipline; associated tools include mock-ups, vibration tables, test benches, prototypes, decompression chamber, wind tunnels, etc.
  - **Representation models** are mainly used to simulate the behavior of a system. For example, enhanced functional flow block diagrams (eFFBDs), statecharts, state machine diagrams (based in systems modeling language (SysML)), etc.
  - **Analytical models** are mainly used to establish values of estimates. We can consider the deterministic models and probabilistic models (also known as stochastic models) to be analytical in nature. Analytical models use equations or diagrams to approach the real operation of the system. They can be very simple (addition) to incredibly complicated (probabilistic distribution with several variables).
- **Use right models** depending on the project progress
  - At the beginning of the project, first studies use simple tools, allowing rough approximations which have the advantage of not requiring too much time and effort. These approximations are often sufficient to eliminate unrealistic or outgoing candidate solutions.

- It is progressively necessary over the development of the project to improve precision of data to compare the candidate solutions still competing. The work is more complicated if the level of innovation is high.
- A systems engineer alone cannot model a complex system; he or she must be supported by skilled people from different disciplines involved.

- **Specialist expertise**: When the values of assessment criteria cannot be given in an objective or precise way, or because the subjective aspect is dominating, we can ask specialists for expertise. The estimates proceed in four steps:

1. Select interviewees to collect the opinion of qualified people for the considered field.
2. Draft a questionnaire; a precise questionnaire allows an easy analysis, but a questionnaire that is too closed risks the neglection of significant points.
3. Interview a limited number of specialists with the questionnaire, including an in-depth discussion to get precise opinions.
4. Analyze the data with several different people and compare their impressions until an agreement on a classification of assessment criteria and/or candidate solutions is reached.

Often used analytical models in the context of system analysis are summarized in Table 3.

Table 3. Often Used Analytical Models in the Context of System Analysis. (SEBoK Original)

Type of Model	Description
Deterministic models	• Models containing **statistics** are included in this category. The principle consists of establishing a model based on a significant amount of data and number of results from former projects; they can apply only to system elements/components whose technology already exists. • Models by **analogy** also use former projects. The system element being studied is compared to an already existing system element with known characteristics (cost, reliability, etc.). Then these characteristics are adjusted based on the specialists' expertise. • **Learning curves** allow foreseeing the evolution of a characteristic or a technology. One example of evolution: "Each time the number of produced units is multiplied by two, the cost of this unit is reduced with a certain percentage, generally constant."
Probabilistic models (also called stochastic models)	The theory of probability allows classifying the possible candidate solutions compared to consequences from a set of events as criteria. These models are applicable if the number of criteria is limited and the combination of the possible events is simple. Take care that the sum of probabilities of all events is equal to one for each node.
Multi-criteria decisions models	When the number of criteria is greater than ten, it is recommended that a multi-criteria decision model be established. This model is obtained through the following actions: • Organize the criteria as a hierarchy (or a decomposition tree). • Associate each criterion of each branch of the tree with a relative weight compared to each other of the same level. • Calculate a scalar weight for each leaf criterion of each branch, multiplying all the weights of the branch. • Score every candidate solution on the leaf criteria; sum the scores to get a global score for each candidate solution; compare the scores. • Using a computerized tool allows to perform sensitivity analysis to get a robust choice.

Practical Considerations

Key pitfalls and good practices related to system analysis are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing system analysis are provided in Table 4.

Table 4. Pitfalls with System Analysis. (SEBoK Original)

Pitfall	Description
Analytical modeling is not a decision tool	Analytical modeling gives analytical results from analytical data. It has to be considered as an aid and not as a decision tool.
Models and system levels of decomposition	A model can be well adapted to a level *n* of a system and be incompatible with the model of the higher level which uses the data coming from the lower level. It is essential that the systems engineer ensures the coherence of the various models used.
Optimization is not a sum of optimized elements	The general optimization of the system-of-interest is not the sum of its optimized systems and/or system elements.

Proven Practices

Some proven practices gathered from the references are provided in Table 5.

Table 5. Proven Practices with System Analysis. (SEBoK Original)

Practice	Description
Stay in the operational field	Models can never simulate all the behavior/reactions of a system: they operate only in one limited field with a restricted number of variables. When a model is used, it is always necessary to make sure that the parameters and data inputs are part of the operation field. If not, there is a high risk of irregular outputs.
Evolve models	Models shall evolve during the project: by modification of parameter settings, by entering new data when modified (modification of assessment criteria, functions to perform, requirements, etc.), by the use of new tools when those used reach their limits.
Use several types of models	It is recommended to concurrently use several types of models in order to compare the results and/or to take into account another aspect of the system.
Keep context elements consistent	Results of a simulation shall always be given in their modeling context: tool used, selected assumptions, parameters and data introduced, and variance of the outputs.

System Realization

- Lead Authors:
- John Snoderly and Alan Faisandier
- Contributing Author:
- Rick Adcock

-

System realization activities are conducted to create and test versions of a system as specified by system definition. The activities are grouped and described as generic processes that are performed iteratively and/or concurrently depending on the selected life cycle model. These activities include those required to build a system (system implementation), integrate disparate system elements (system integration), and ensure that the system meets both the needs of stakeholders (system validation) and aligns with the system requirements and architecture (system verification).

These activities are not sequential, but are performed concurrently, iteratively and recursively depending on the selected life cycle model. Figure 1 (see "Overview", below), also shows how these processes fit within the context of system definition and System Deployment and Use KAs. See also Applying Life Cycle Processes for further discussion of the relationships between process and life cycle model.

Topics

Each part of the SEBoK is divided into KAs, which are groupings of information with a related theme. The KAs in turn are divided into topics. This KA contains the following topics:

- System Implementation
- System Integration
- System Verification
- System Validation

See the article Matrix of Implementation Examples for a mapping of case studies and vignettes included in Part 7 to topics covered in Part 3.

Overview

Essentially, the outputs of system definition are used during system implementation to create system elements and during system integration to provide plans and criteria for combining these elements. The requirements are used to verify and validate system elements, systems, and the overall system-of-interest (SoI). These activities provide feedback into the system design, particularly when problems or challenges are identified.

Finally, when the system is considered, verified, and validated, it will then become an input to system deployment and use. It is important to understand that there is overlap in these activities; they do not have to occur in sequence as demonstrated in Figure 1. Every life cycle model includes realization activities, principally, verification and validation activities. The way these activities are performed is dependent upon the life cycle model in use. (For additional information on life cycles, see the Life Cycle Models KA.)

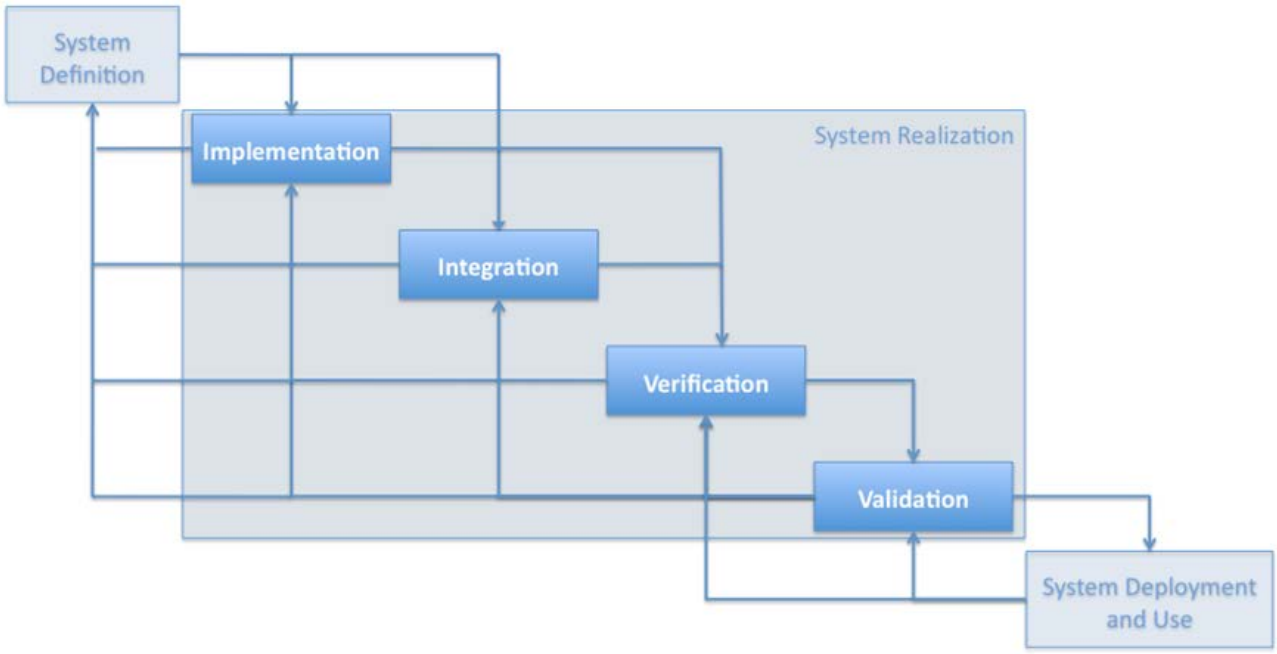

Figure 1. System Realization. (SEBoK Original)

The realization processes are performed to ensure that the system will be ready for transition and has the appropriate structure and behavior to enable the desired operation and functionality throughout the system's life span. Both DAU and NASA include transition in realization, in addition to implementation, integration, verification, and validation (Prosnik 2010; NASA December 2007, 1-360).

Fundamentals

Macro View of Realization Processes

Figure 2 illustrates a macro view of generic outputs from realization activities when using a Vee life cycle model. The left side of the Vee represents various design activities 'going down' the system.

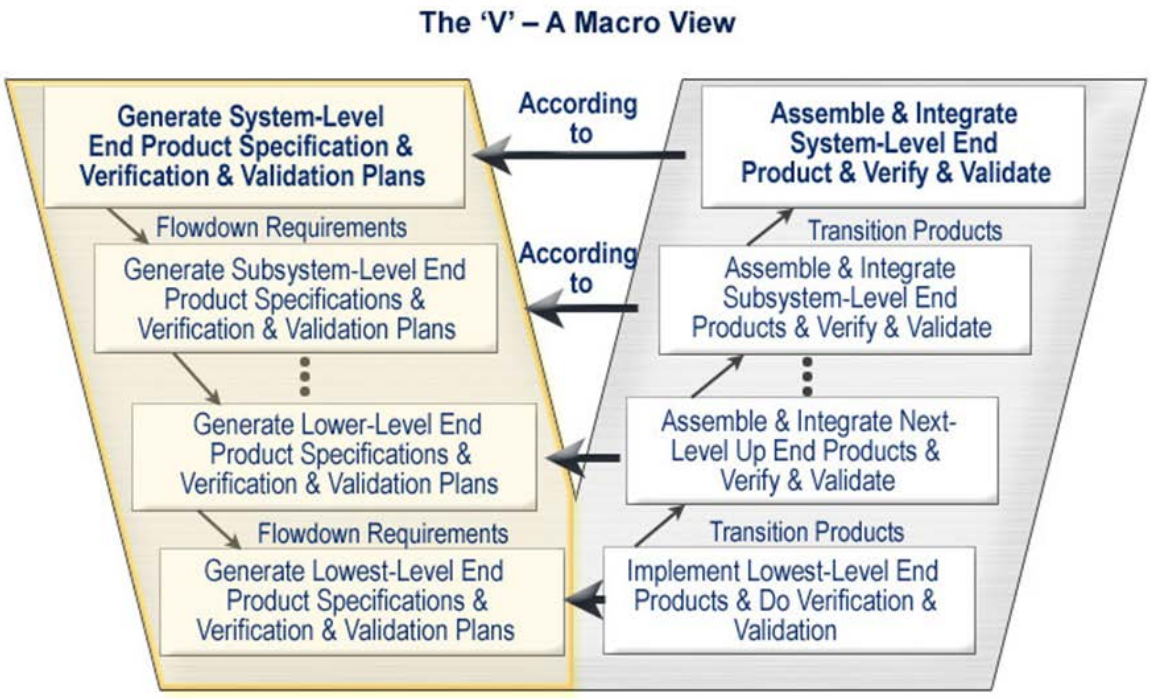

Figure 2. The Vee Activity Diagram (Prosnik 2010). Released by the Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

The left side of the Vee model demonstrates the development of system elements specifications and design descriptions. In this stage, verification and validation plans are developed, which are later used to determine whether realized system elements (products, services, or enterprises) are compliant with specifications and stakeholder needs and requirements. Also, during this stage initial specifications become flow-down requirements for lower-level system models. In terms of time frame, these activities take place early in the system's life cycle. These activities are discussed further in the System Definition KA. However, it is important to understand that some of the system realization activities are initiated at the same time as system definition activities; this is the case with integration, verification and validation planning in particular.

The right side of the Vee model, as illustrated in Figure 2, shows the system elements (products, services, or enterprises) are assembled according to the system model described on the left side of the Vee (integration). Verification and validation activities determine how well the realized system fulfills the stakeholder requirements, the system requirements, and design properties. These activities should follow the plans developed on the left side of the Vee. Integration can be done continuously, incrementally and/or iteratively, supported by verification and validation (V&V) efforts. For example, integration typically starts at the bottom of the Vee and continues upwards to the top of the Vee.

The U.S. Defense Acquisition University (DAU) provides an overview of what occurs during system realization:

> *Once the products of all system models have been fully defined, Bottom-Up End Product Realization can be initiated. This begins by applying the Implementation Process to buy, build, code or reuse end products. These implemented end products are verified against their design descriptions and specifications, validated against Stakeholder Requirements and then transitioned to the next higher*

> *system model for integration. End products from the Integration Process are successively integrated upward, verified and validated, transitioned to the next acquisition phase or transitioned ultimately as the End Product to the user.* (Prosnik 2010)

While the systems engineering (SE) technical processes are life cycle processes, the processes are concurrent, and the emphasis of the respective processes depends on the phase and maturity of the design. Figure 3 portrays (from left to right) a notional emphasis of the respective processes throughout the systems acquisition life cycle from the perspective of the U.S. Department of Defense (DoD). It is important to note that from this perspective, these processes do not follow a linear progression; instead, they are concurrent, with the amount of activity in a given area changing over the system's life cycle. The red boxes indicate the topics that will be discussed as part of realization.

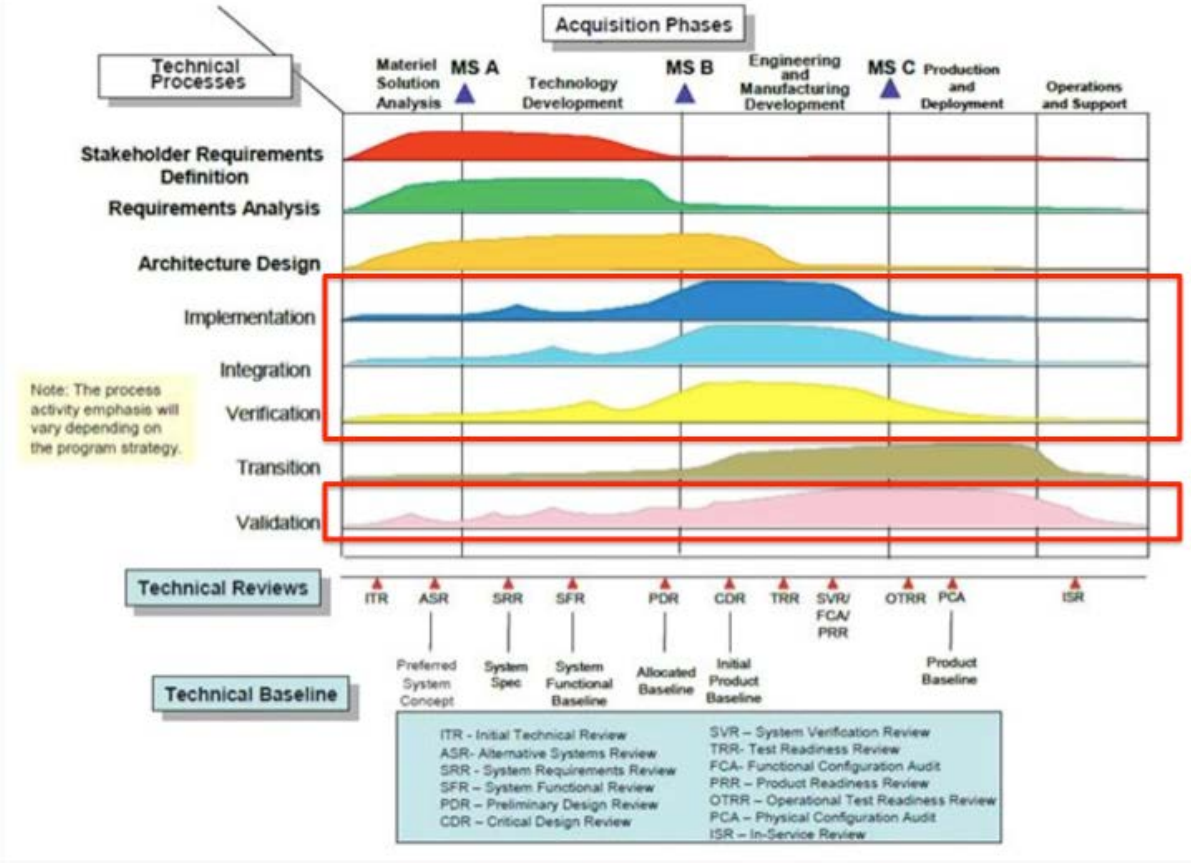

Figure 3. Notional Emphasis of Systems Engineering Technical Processes and Program Life-Cycle Phases (DAU 2010). Released by the Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

System Implementation

- Lead Authors:
- John Snoderly and Alan Faisandier

-

System Implementation uses the structure created during architectural design and the results of system analysis to construct system elements that meet the stakeholder needs and requirements and system requirements developed in the early life cycle phases. These system elements are then integrated to form intermediate aggregates and finally the complete system-of-interest (SoI). See System Integration.

Definition and Purpose

Implementation is the process that actually yields the lowest-level system elements in the system hierarchy (system breakdown structure). System elements are made, bought, or reused. Production involves the hardware fabrication processes of forming, removing, joining, and finishing, the software realization processes of coding and testing, or the operational procedures development processes for operators' roles. If implementation involves a production process, a manufacturing system which uses the established technical and management processes may be required.

The purpose of the implementation process is to design and create (or fabricate) a system element conforming to that element's design properties and/or requirements. The element is constructed employing appropriate technologies and industry practices. This process bridges the system definition processes and the integration process. Figure 1 portrays how the outputs of system definition relate to system implementation, which produces the implemented (system) elements required to produce aggregates and the SoI.

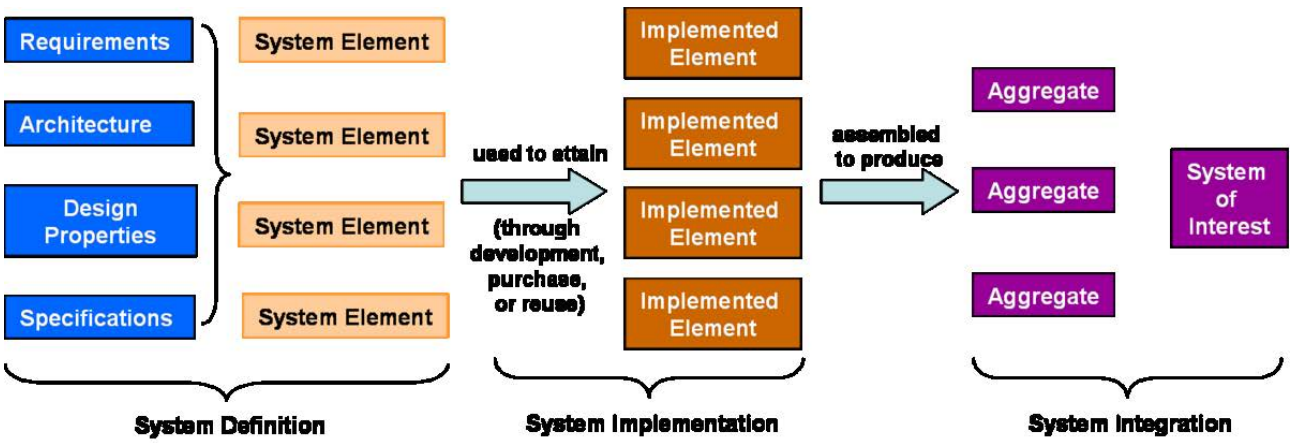

Figure 1. Simplification of How the Outputs of System Definition Relate to System Implementation, which Produces the System Elements Required to Produce Systems and Subsystems. (SEBoK Original)

Process Approach

Purpose and Principle of the Approach

During the implementation process, engineers apply the design properties and/or requirements allocated to a system element to design and produce a detailed description. They then fabricate, code, or build each individual element using specified materials, processes, physical or logical arrangements, standards, technologies, and/or information flows outlined in detailed descriptions (drawings or other design documentation). A system element will be verified against the detailed description of properties and validated against its requirements.

If subsequent verification and validation (V&V) actions or configuration audits reveal discrepancies, recursive interactions occur, which includes predecessor activities or processes, as required, to mitigate those discrepancies and to modify, repair, or correct the system element in question. Figure 2 provides the context for the implementation process from the perspective of the U.S. Defense Acquisition University (DAU).

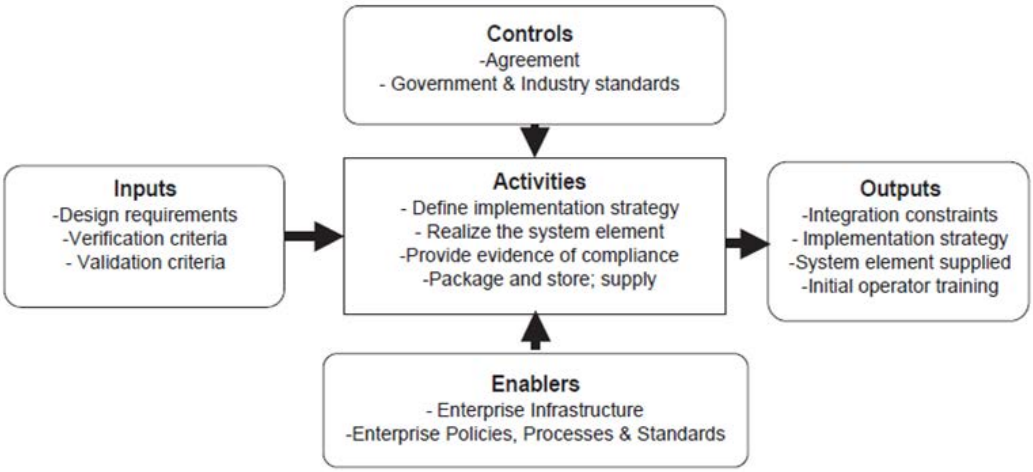

Figure 2. Context Diagram for the Implementation Process (DAU 2010). Released by the Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

Such figures provide a useful overview of the systems engineering (SE) community's perspectives on what is required for implementation and what the general results of implementation may be. These are further supported by the discussion of implementation inputs, outputs, and activities found in the National Aeronautics and Space

Association's (NASA's) *Systems Engineering Handbook* (NASA 2007). It is important to understand that these views are process -oriented. While this is a useful model, examining implementation only in terms of process can be limiting.

Depending on the technologies and systems chosen when a decision is made to produce a system element, the implementation process outcomes may generate constraints to be applied on the architecture of the higher-level system; those constraints are normally identified as derived system requirements and added to the set of system requirements applicable to this higher-level system. The architectural design has tomust take those constraints into account.

If the decision is made to purchase or reuse an existing system element, it has tomust be identified as a constraint or system requirement applicable to the architecture of the higher-level system. Conversely, the implementation process may involve some adaptation or adjustments to the system requirement in order to be integrated into a higher-level system or aggregate.

Implementation also involves packaging, handling, and storage, depending on the concerned technologies and where or when the system requirement needs to be integrated into a higher-level aggregate. Developing the supporting documentation for a system requirement, such as the manuals for operation, maintenance, and/or installation, is also a part of the implementation process; these artifacts are utilized in the system deployment and use phase. The system element requirements and the associated verification and validation criteria are inputs to this process; these inputs come from the architectural design process detailed outputs.

Execution of the implementation process is governed by both industrial and government standards and the terms of all applicable agreements. This may include conditions for packaging and storage, as well as preparation for use activities, such as operator training. In addition, packaging, handling, storage, and transportation (PHS&T) considerations will constrain the implementation activities. For more information, refer to the discussion of PHS&T in the System Deployment and Use article. The developing or integrating organization will likely have enterprise-level safety practices and guidelines that must also be considered.

Activities of the Process

The following major activities and tasks are performed during this process:

- **Define the implementation strategy** - Implementation process activities begin with detailed design and include developing an implementation strategy that defines fabrication and coding procedures, tools and equipment to be used, implementation tolerances, and the means and criteria for auditing configuration of resulting elements to the detailed design documentation. In the case of repeated system element implementations (such as for mass manufacturing or replacement elements), the implementation strategy is defined and refined to achieve consistent and repeatable element production; it is retained in the project decision database for future use. The implementation strategy contains the arrangements for packing, storing, and supplying the implemented element.
- **Realize the system element** - Realize or adapt and produce the concerned system element using the implementation strategy items as defined above. Realization or adaptation is conducted with regard to standards that govern applicable safety, security, privacy, and environmental guidelines or legislation and the practices of the relevant implementation technology. This requires the fabrication of hardware elements, development of software elements, definition of training capabilities, drafting of training documentation, and the training of initial operators and maintainers.
- **Provide evidence of compliance** - Record evidence that the system element meets its requirements and the associated verification and validation criteria as well as the legislation policy. This requires the conduction of peer reviews and unit testing, as well as inspection of operation and maintenance manuals. Acquire measured properties that characterize the implemented element (weight, capacities, effectiveness, level of performance, reliability, availability, etc.).
- **Package, store, and supply the implemented element** - This should be defined in the implementation strategy.

Artifacts and Ontology Elements

This process may create several artifacts such as:

- an implemented system
- implementation tools
- implementation procedures
- an implementation plan or strategy
- verification reports
- issue, anomaly, or trouble reports
- change requests (about design)

This process handles the ontology elements shown in Table 1 below.

Table 1. Main Ontology Elements as Handled within System Element Implementation. (SEBoK Original)

Element	Definition
	Attributes (examples)
Implemented Element	An implemented element is a system element that has been implemented. In the case of hardware it is marked with a part/serial number.
	Identifier, name, description, type (hardware, software application, software piece, mechanical part, electric art, electronic component, operator role, procedure, protocol, manual, etc.)
Measured Property	A measured property is a characteristic of the implemented element established after its implementation. The measured properties characterize the implemented system element when it is completely realized, verified, and validated. If the implemented element complies with a design property, the measured property should equal the design property. Otherwise one has tomust identify the difference or non-conformance which treatment could conclude to modify the design property and possibly the related requirements, or to modify (correct, repair) the implemented element, or to identify a deviation.
	Identifier, name, description, type (effectiveness, availability, reliability, maintainability, weight, capacity, etc.), value, unit, etc.

The main relationships between ontology elements are presented in Figure 3.

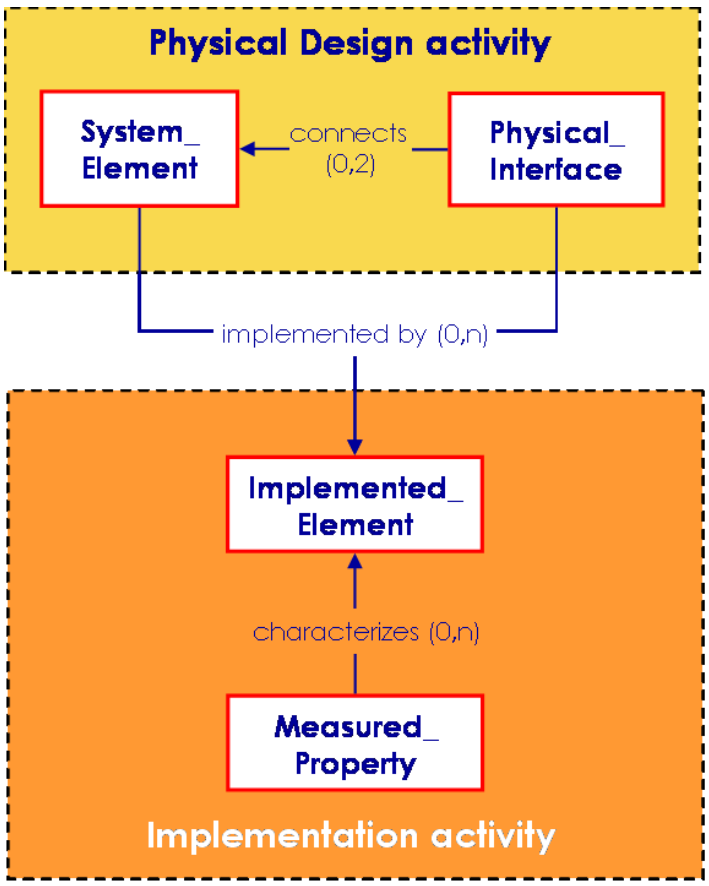

Figure 3. Implementation Elements Relationships with Other Engineering Elements. (SEBoK Original)

Methods, Techniques, and Tools

There are many software tools available in the implementation and integration phases. The most basic method would be the use of N-squared diagrams as discussed in Jeff Grady's book *System Integration* (Grady 1994).

Checking and Correctness of Implementation

Proper implementation checking and correctness should include testing to determine if the implemented element (i.e., piece of software, hardware, or other product) works in its intended use. Testing could include mockups and breadboards, as well as modeling and simulation of a prototype or completed pieces of a system. Once this is completed successfully, the next process would be system integration.

System Integration

- Lead Authors:
- John Snoderly, Alan Faisandier, and Scott Jackson

-

System integration consists of taking delivery of the implemented system elements which compose the system-of-interest (SoI), assembling these implemented elements together, and performing the verification and validation actions (V&V actions) in the course of the assembly. The ultimate goal of system integration is to ensure that the individual system elements function properly as a whole and satisfy the design properties or characteristics of the system. System integration is one part of the realization effort and relates only to developmental items. Integration should not to be confused with the assembly of end products on a production line. To perform the production, the assembly line uses a different order from that used by integration.

Definition and Purpose

System integration consists of a process that "*iteratively combines implemented system elements to form complete or partial system configurations in order to build a product or service. It is used recursively for successive levels of the system hierarchy*." (ISO/IEC 15288 2015, 68). The process is extended to any kind of product system, service system, and enterprise system. The purpose of system integration is to prepare the SoI for final validation and transition either for use or for production. Integration consists of progressively assembling aggregates of implemented elements that compose the SoI as architected during design, and to check correctness of static and dynamic aspects of interfaces between the implemented elements.

The U.S. Defense Acquisition University (DAU) provides the following context for integration: *The integration process will be used . . . for the incorporation of the final system into its operational environment to ensure that the system is integrated properly into all defined external interfaces. The interface management process is particularly important for the success of the integration process, and iteration between the two processes will occur* (DAU 2010).

The purpose of system integration can be summarized as below:

- Completely assemble the implemented elements to make sure that the they are compatible with each other.
- Demonstrate that the aggregates of implemented elements perform the expected functions and meet measures of performance/effectiveness.
- Detect defects/faults related to design and assembly activities by submitting the aggregates to focused V&V actions.

Note: In the systems engineering literature, sometimes the term *integration* is used in a larger context than in the present topic. In this larger sense, it concerns the technical effort to simultaneously design and develop the system and the processes for developing the system through concurrent consideration of all life cycle stages, needs, and competences. This approach requires the "integration" of numerous skills, activities, or processes.

Principles

Boundary of Integration Activity

Integration can be understood as the whole bottom-up branch of the Vee Model, including the tasks of assembly and the appropriate verification tasks. See Figure 1 below:

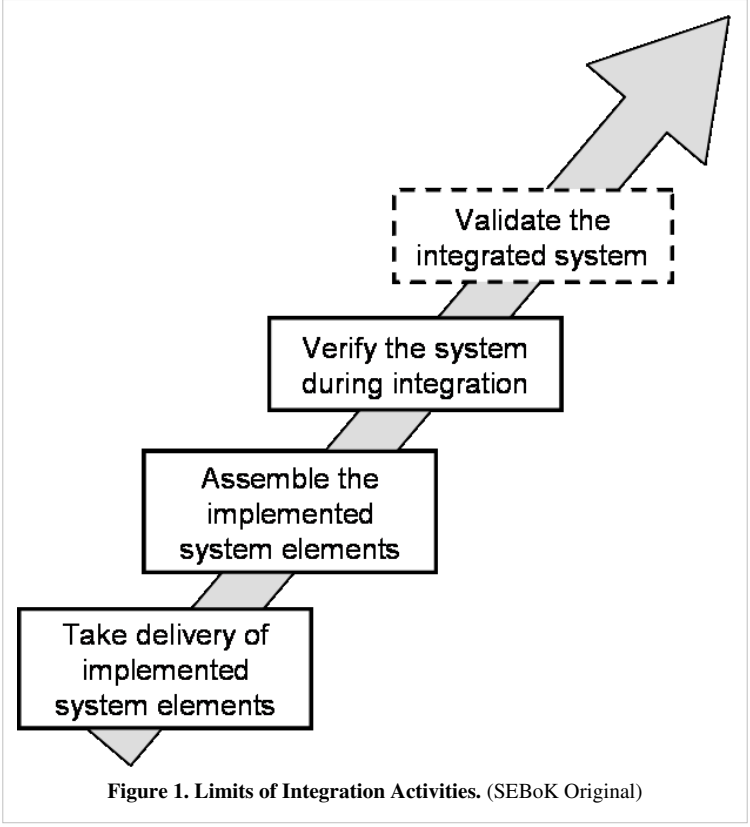

Figure 1. Limits of Integration Activities. (SEBoK Original)

The assembly activity joins together, and physically links, the implemented elements. Each implemented element is individually verified and validated prior to entering integration. Integration then adds the verification activity to the assembly activity, excluding the final validation.

The final validation performs operational tests that authorize the transition for use or the transition for production. Remember that system integration only endeavors to obtain pre-production prototypes of the concerned product, service, or enterprise. If the product, service, or enterprise is delivered as a unique exemplar, the final validation activity serves as acceptance for delivery and transfer for use. If the prototype has to be produced in several exemplars, the final validation serves as acceptance to launch their production. The definition of the optimized operations of assembly which will be carried out on a production line relates to the manufacturing process and not to the integration process.

Integration activity can sometimes reveal issues or anomalies that require modifications of the design of the system. Modifying the design is not part of the integration process but concerns only the design process. Integration only deals with the assembly of the implemented elements and verification of the system against its properties as designed. During assembly, it is possible to carry out tasks of finishing touches which require simultaneous use of several implemented elements (e.g., paint the whole after assembly, calibrate a biochemical component, etc.). These

tasks must be planned in the context of integration and are not carried out on separate implemented elements and do not include modifications related to design.

Aggregation of Implemented Elements

The integration is used to systematically assemble a higher-level system from lower-level ones (implemented system elements) that have been implemented. Integration often begins with analysis and simulations (e.g., various types of prototypes) and progresses through increasingly more realistic systems and system elements until the final product, service, or enterprise is achieved.

System integration is based on the notion of an aggregate - a subset of the system made up of several implemented elements (implemented system elements and physical interfaces) on which a set of V&V actions is applied. Each aggregate is characterized by a configuration which specifies the implemented elements to be physically assembled and their configuration status.

To perform V&V actions, a V&V configuration that includes the aggregate plus V&V tools is constituted. The V&V tools are enabling products and can be simulators (simulated implemented elements), stubs or caps, activators (launchers, drivers), harness, measuring devices, etc.

Integration by Level of System

According to the Vee Model, system definition (top-down branch) is done by successive levels of decomposition; each level corresponds to the physical architecture of systems and system elements. The integration (bottom-up branch) takes the opposite approach of composition (i.e., a level by level approach). On a given level, integration is done on the basis of the physical architecture defined during system definition.

Integration Strategy

The integration of implemented elements is generally performed according to a predefined strategy. The definition of the integration strategy is based on the architecture of the system and relies on the way the architecture of the system has been designed. The strategy is described in an integration plan that defines the minimum configuration of expected aggregates, the order of assembly of these aggregates in order to support efficient subsequent verification and validation actions (e.g., inspections and/or testing), techniques to check or evaluate interfaces, and necessary capabilities in the integration environment to support combinations of aggregates. The integration strategy is thus elaborated starting from the selected verification and validation strategy. See the System Verification and System Validation topics.

To define an integration strategy, there are several possible integration approaches/techniques that may be used individually or in combination. The selection of integration techniques depends on several factors; in particular, the type of system element, delivery time, order of delivery, risks, constraints, etc. Each integration technique has strengths and weaknesses which should be considered in the context of the SoI. Some integration techniques are summarized in Table 1 below.

Table 1. Integration Techniques. (SEBoK Original)

Integration Technique	Description
Global Integration	Also known as *big-bang integration*; all the delivered implemented elements are assembled in only one step. • This technique is simple and does not require simulating the implemented elements not being available at that time. • Difficult to detect and localize faults; interface faults are detected late. • Should be reserved for simple systems, with few interactions and few implemented elements without technological risks.
Integration "with the Stream"	The delivered implemented elements are assembled as they become available. • Allows starting the integration quickly. • Complex to implement because of the necessity to simulate the implemented elements not yet available. Impossible to control the end-to-end "functional chains"; consequently, global tests are postponed very late in the schedule. • Should be reserved for well-known and controlled systems without technological risks.
Incremental Integration	In a predefined order, either one or a very few implemented elements are added to an already integrated increment of implemented elements. • Fast localization of faults: a new fault is usually localized in lately integrated implemented elements or dependent of a faulty interface. • Require simulators for absent implemented elements. Require many test cases, as each implemented element addition requires the verification of the new configuration and regression testing. • Applicable to any type of architecture.
Subsets Integration	Implemented elements are assembled by subsets, and then subsets are assembled together (a subset is an aggregate); could also be called "functional chains integration". • Time saving due to parallel integration of subsets; delivery of partial products is possible. Requires less means and fewer test cases than integration by increments. • Subsets shall be defined during the design. • Applicable to architectures composed of sub-systems.
Top-Down Integration	Implemented elements or aggregates are integrated in their activation or utilization order. • Availability of a skeleton and early detection of architectural faults, definition of test cases close to reality, and the re-use of test data sets possible. • Many stubs/caps need to be created; difficult to define test cases of the leaf-implemented elements (lowest level). • Mainly used in software domain. Start from the implemented element of higher level; implemented elements of lower level are added until leaf-implemented elements.
Bottom-Up Integration	Implemented elements or aggregates are integrated in the opposite order of their activation or utilization. • Easy definition of test cases; early detection of faults (usually localized in the leaf-implemented elements); reduce the number of simulators to be used. An aggregate can be a sub-system. • Test cases shall be redefined for each step, drivers are difficult to define and realize, implemented elements of lower levels are "over-tested", and does not allow architectural faults to be quickly detected. • Mainly used in software domain, but can be used in any kind of system.
Criterion Driven Integration	The most critical implemented elements compared to the selected criterion are first integrated (dependability, complexity, technological innovation, etc.). Criteria are generally related to risks. • Allows early and intensive testing of critical implemented elements; early verification of design choices. • Test cases and test data sets are difficult to define.

Usually, a mixed integration technique is selected as a trade-off between the different techniques listed above, allowing optimization of work and adaptation of the process to the system under development. The optimization takes into account the realization time of the implemented elements, their delivery scheduled order, their level of complexity, the technical risks, the availability of assembly tools, cost, deadlines, specific personnel capability, etc.

Process Approach

Activities of the Process

Major activities and tasks performed during this process include:

- **Establishing the integration plan** (this activity is carried out concurrently to the design activity of the system) that defines:
  - The optimized integration strategy – order of aggregates assembly using appropriate integration techniques.
  - The V&V actions to be processed for the purpose of integration.
  - The configurations of the aggregates to be assembled and verified.
  - The integration means and verification means (dedicated enabling products) that may include assembly procedures, assembly tools (harness, specific tools), V&V tools (simulators, stubs/caps, launchers, test benches, devices for measuring, etc.), and V&V procedures.
- **Obtain the integration means** and verification means as defined in the integration plan. The acquisition of the means can be accomplished through various ways such as procurement, development, reuse, and sub-contracting; usually the acquisition of the complete set of means is a mix of these methods.
- **Take delivery** of each implemented element:
  - Unpack and reassemble the implemented element with its accessories.
  - Check the delivered configuration, conformance of implemented elements and compatibility of interfaces, and ensure the presence of mandatory documentation.
- **Assemble the implemented elements** into aggregates:
  - Gather the implemented elements to be assembled, the integration means (assembly tools, assembly procedures), and the verification means (V&V tools and procedures).
  - Connect the implemented elements to each other using assembly tools to constitute aggregates in the order prescribed by the integration plan and in assembly procedures.
  - Add or connect the V&V tools to the aggregates as predefined.
  - Carry out eventual operations of welding, gluing, drilling, tapping, adjusting, tuning, painting, parametering, etc.
- **Verify each aggregate**:
  - Check the aggregate is correctly assembled according to established procedures.
  - Perform the verification process that uses verification and validation procedures and check that the aggregate shows the right design properties/specified requirements.
  - Record integration results/reports and potential issue reports, change requests, etc.

Artifacts and Ontology Elements

This process may create several artifacts such as:

- an integrated system
- assembly tools
- assembly procedures
- integration plans
- integration reports
- issue/anomaly/trouble reports
- change requests (about design)

This process utilizes the ontology elements discussed in Table 2.

Table 2. Main Ontology Elements as Handled within System Integration. (SEBoK Original)

Element	Definition
	Attributes
Aggregate	An aggregate is a subset of the system made up of several system elements or systems on which a set of verification actions is applied.
	Identifier, name, description
Assembly Procedure	An assembly procedure groups a set of elementary assembly actions to build an aggregate of implemented system elements.
	Identifier, name, description, duration, unit of time
Assembly Tool	An assembly tool is a physical tool used to connect, assemble, or link several implemented system elements to build aggregates (specific tool, harness, etc.).
	Identifier, name, description
Risk	An event having a probability of occurrence and a gravity degree on its consequence onto the system mission or on other characteristics (used for technical risk in engineering). A risk is the combination of vulnerability and of a danger or a threat.
	Identifier, name, description, status
Rationale	An argument that provides the justification for the selection of an engineering element.
	Identifier, name, description (rationale, reasons for defining an aggregate, assembly procedure, assembly tool)

Note: verification and validation ontology elements are described in the System Verification and System Validation topics.

The main relationships between ontology elements are presented in Figure 2.

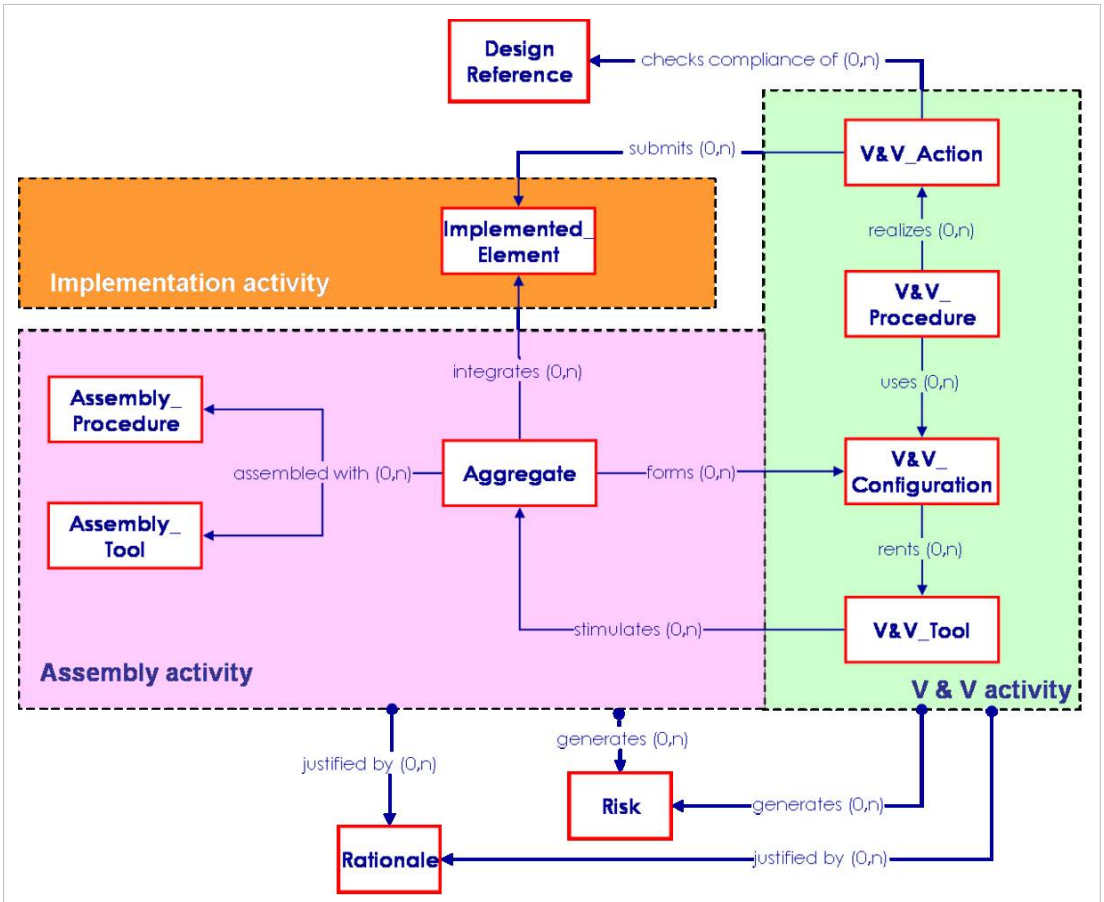

Figure 2. Integration Elements Relationships with Other Engineering Elements. (SEBoK Original)

Checking and Correctness of Integration

The main items to be checked during the integration process include the following:

- The integration plan respects its template.
- The expected assembly order (integration strategy) is realistic.
- No system element and physical interface set out in the system design document is forgotten.
- Every interface and interaction between implemented elements is verified.
- Assembly procedures and assembly tools are available and validated prior to beginning the assembly.
- V&V procedures and tools are available and validated prior to beginning the verification.
- Integration reports are recorded.

Methods and Techniques

Several different approaches are summarized above in the section Integration Strategy [1] (above) that may be used for integration, yet other approaches exist. In particular, important integration strategies for intensive software systems include: vertical integration, horizontal integration, and star integration.

Coupling Matrix and N-squared Diagram

One of the most basic methods to define the aggregates and the order of integration would be the use of N-Squared diagrams (Grady 1994, 190).

In the integration context, the coupling matrices are useful for optimizing the aggregate definition and verification of interfaces:

- The integration strategy is defined and optimized by reorganizing the coupling matrix in order to group the implemented elements in aggregates, thus minimizing the number of interfaces to be verified between aggregates (see Figure 3).

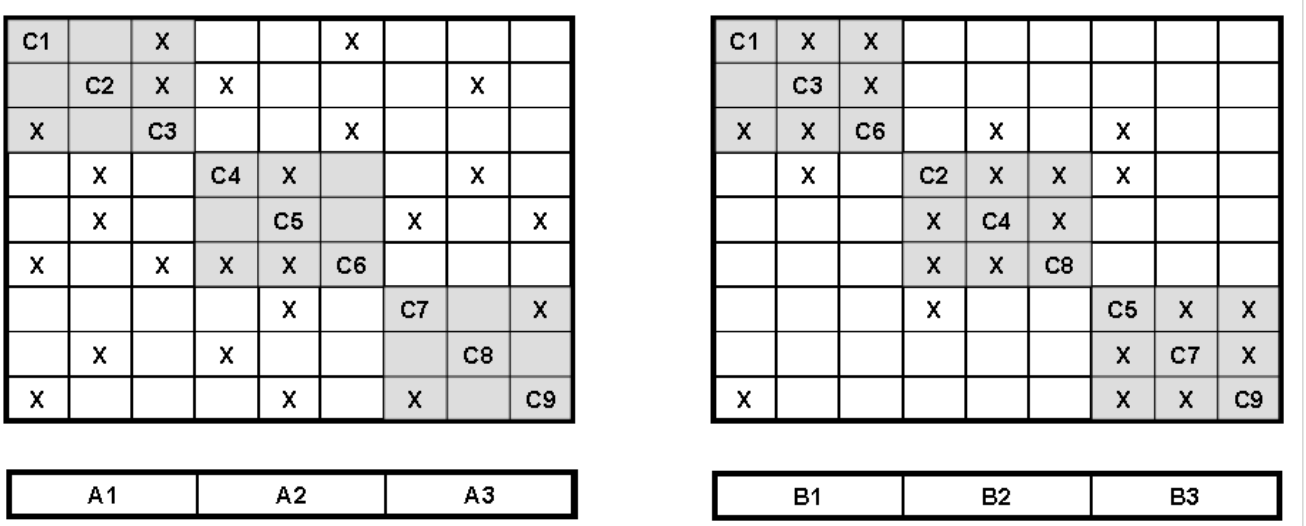

Figure 3. Initial Arrangement of Aggregates on the Left; Final Arrangement After Reorganization on the Right. (SEBoK Original)

- When verifying the interactions between aggregates, the matrix is an aid tool for fault detection. If by adding an implemented element to an aggregate an error is detected, the fault can be related to the implemented element, to the aggregate, or to the interfaces. If the fault is related to the aggregate, it can relate to any implemented element or any interface between the implemented elements internal to the aggregate.

Application to Product Systems, Service Systems, and Enterprise Systems

As the nature of implemented system elements and physical interfaces is different for these types of systems, the aggregates, the assembly tools, and the V&V tools are different. Some integration techniques are more appropriate to specific types of systems. Table 3 below provides some examples.

Table 3. Different Integration Elements for Product, Service, and Enterprise Systems. (SEBoK Original)

Element	Product System	Service System	Enterprise System
System Element	Hardware Parts (mechanics, electronics, electrical, plastic, chemical, etc.) Operator Roles Software Pieces	Processes, data bases, procedures, etc. Operator Roles Software Applications	Corporate, direction, division, department, project, technical team, leader, etc. IT components
Physical Interface	Hardware parts, protocols, procedures, etc.	Protocols, documents, etc.	Protocols, procedures, documents, etc.
Assembly Tools	Harness, mechanical tools, specific tools Software Linker	Documentation, learning course, etc.	Documentation, learning, moving of office
Verification Tools	Test bench, simulator, launchers, stub/cap	Activity/scenario models, simulator, human roles rehearsal, computer, etc. Skilled Experts	Activity/scenario models, simulator, human roles rehearsal
Validation Tools	Operational environment	Operational environment	Operational environment

Recommended Integration Techniques	Top down integration technique Bottom Up Integration technique	Subsets integration technique (functional chains)	Global integration technique Incremental integration

Practical Considerations

Key pitfalls and good practices related to system integration are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing SE Measurement are provided in Table 4.

Table 4. Major Pitfalls with System Integration. (SEBoK Original)

Pitfall	Description
Delay of expected element	The experience shows that the implemented elements always do not arrive in the expected order and the tests never proceed or result as foreseen; therefore, the integration strategy should allow a great flexibility.
Big-bang not appropriate	The "big-bang" integration technique is not appropriate for a fast detection of faults. It is thus preferable to verify the interfaces progressively all along the integration.
Integration plan too late	The preparation of the integration activities is planned too late in the project schedule, typically when first implemented elements are delivered.

Good Practices

Some good practices gathered from the references are provided in Table 5.

Table 5. Proven Practices with System Integration. (SEBoK Original)

Practice	Description
Start earlier development of means	The development of assembly tools and verification and validation tools can be take as long as the system development itself. It should be started as early as possible as soon as the preliminary design is nearly frozen.
Integration means seen as enabling systems	The development of integration means (assembly tools, verification, and validation tools) can be seen as enabling systems, using system definition and system realization processes as described in this SEBoK, and managed as projects. These projects can be led by the project of the corresponding system-of-interest, but assigned to specific system blocks, or can be subcontracted as separate projects.
Use coupling matrix	A good practice consists in gradually integrating aggregates in order to detect faults more easily. The use of the coupling matrix applies for all strategies and especially for the bottom up integration strategy.
Flexible integration plan and schedule	The integration process of complex systems cannot be easily foreseeable and its progress control difficult to observe. This is why it is recommended to plan integration with specific margins, using flexible techniques, and integrating sets by similar technologies.
Integration and design teams	The integration responsible should be part of the design team.

System Verification

- Lead Authors:
- John Snoderly and Alan Faisandier

-

System Verification is a set of actions used to check the *correctness* of any element, such as a system element, a system, a document, a service, a task, a requirement, etc. These types of actions are planned and carried out throughout the life cycle of the system. Verification is a generic term that needs to be instantiated within the context it occurs. As a process, verification is a transverse activity to every life cycle stage of the system. In particular, during the development cycle of the system, the verification process is performed in parallel with the system definition and system realization processes and applies to any activity and any product resulting from the activity. The activities of every life cycle process and those of the verification process can work together. For example, the integration process frequently uses the verification process. It is important to remember that verification, while separate from validation, is intended to be performed in conjunction with validation.

Definition and Purpose

Verification is the confirmation, through the provision of objective evidence, that specified requirements have been fulfilled. With a note added in ISO/IEC/IEEE 15288, the scope of verification includes a set of activities that compares a system or system element against the requirements, architecture and design characteristics, and other properties to be verified (ISO/IEC/IEEE 2015). This may include, but is not limited to, specified requirements, design description, and the system itself.

The purpose of verification, as a generic action, is to identify the faults/defects introduced at the time of any transformation of inputs into outputs. Verification is used to provide information and evidence that the transformation was made according to the selected and appropriate methods, techniques, standards, or rules.

Verification is based on tangible evidence; i.e., it is based on information whose veracity can be demonstrated by factual results obtained from techniques such as inspection, measurement, testing, analysis, calculation, etc. Thus, the process of verifying a system (product, service, enterprise, or system of systems (SoS)) consists of comparing the realized characteristics or properties of the product, service, or enterprise against its expected design properties.

Principles and Concepts

Concept of Verification Action

Why Verify?

In the context of human realization, any human thought is susceptible to error. This is also the case with any engineering activity. Studies in human reliability have shown that people trained to perform a specific operation make around 1-3 errors per hour in best case scenarios. In any activity, or resulting outcome of an activity, the search for potential errors should not be neglected, regardless of whether or not one thinks they will happen or that they should not happen; the consequences of errors can cause extremely significant failures or threats.

A **verification action** is defined, and then performed, as shown in Figure 1.

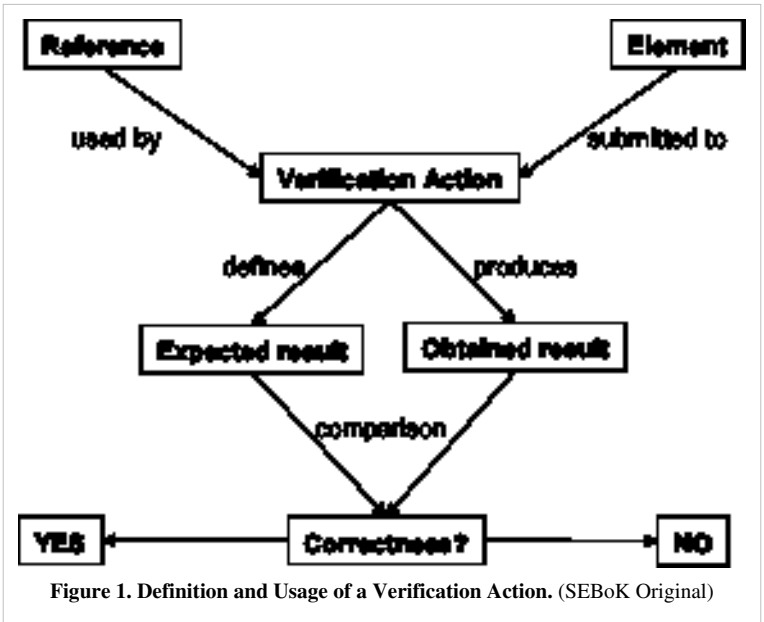

Figure 1. Definition and Usage of a Verification Action. (SEBoK Original)

The definition of a verification action applied to an engineering element includes the following:

- Identification of the element on which the verification action will be performed
- Identification of the reference to define the expected result of the verification action (see examples of reference in Table 1)

The performance of a verification action includes the following:

- Obtaining a result by performing the verification action onto the submitted element
- Comparing the obtained result with the expected result
- Deducing the degree of correctness of the element

What to Verify?

Any engineering element can be verified using a specific reference for comparison: stakeholder requirement, system requirement, function, system element, document, etc. Examples are provided in Table 1.

Table 1. Examples of Verified Items. (SEBoK Original)

Items	Explanation for Verification
Document	To verify a document is to check the application of drafting rules.
Stakeholder Requirement and System Requirement	To verify a stakeholder requirement or a system requirement is to check the application of syntactic and grammatical rules, characteristics defined in the stakeholder requirements definition process, and the system requirements definition process such as necessity, implementation free, unambiguous, consistent, complete, singular, feasible, traceable, and verifiable.
Design	To verify the design of a system is to check its logical and physical architecture elements against the characteristics of the outcomes of the design processes.
System	To verify a system (product, service, or enterprise) is to check its realized characteristics or properties against its expected design characteristics.
Aggregate	To verify an aggregate for integration is to check every interface and interaction between implemented elements.
Verification Procedure	To verify a verification procedure is to check the application of a predefined template and drafting rules.

Verification versus Validation

The term *verification* is often associated with the term *validation* and understood as a single concept of *V&V*. Validation is used to ensure that *one is working the right problem*, whereas verification is used to ensure that *one has solved the problem right* (Martin 1997). From an actual and etymological meaning, the term verification comes from the Latin *verus*, which means truth, and *facere*, which means to make/perform. Thus, verification means to prove that something is *true* or correct (a property, a characteristic, etc.). The term validation comes from the Latin *valere*, which means to become strong, and has the same etymological root as the word *value*. Thus, validation means to prove that something has the right features to produce the expected effects. (Adapted from "Verification and Validation in plain English" (Lake INCOSE 1999).)

The main differences between the verification process and the validation process concern the references used to check the correctness of an element, and the acceptability of the effective correctness.

- Within verification, comparison between the expected result and the obtained result is generally binary, whereas within validation, the result of the comparison may require a judgment of value regarding whether or not to accept the obtained result compared to a threshold or limit.
- Verification relates more to one element, whereas validation relates more to a set of elements and considers this set as a whole.
- Validation presupposes that verification actions have already been performed.
- The techniques used to define and perform the verification actions and those for validation actions are very similar.

Integration, Verification, and Validation of the System

There is sometimes a misconception that verification occurs after integration and before validation. In most cases, it is more appropriate to begin verification activities during development or implementation and to continue them into deployment and use.

Once the system elements have been realized, they are integrated to form the complete system. Integration consists of assembling and performing verification actions as stated in the integration process. A final validation activity generally occurs when the system is integrated, but a certain number of validation actions are also performed parallel to the system integration in order to reduce the number of verification actions and validation actions while controlling the risks that could be generated if some checks are excluded. Integration, verification, and validation are intimately processed together due to the necessity of optimizing the strategy of verification and validation, as well as the strategy of integration.

Process Approach

Purpose and Principle of the Approach

The purpose of the verification process is to confirm that the system fulfills the specified design requirements. This process provides the information required to effect the remedial actions that correct non-conformances in the realized system or the processes that act on it - see ISO/IEC/IEEE 15288 (ISO/IEC/IEEE 2015).

Each system element and the complete system itself should be compared against its own design references (specified requirements). As stated by Dennis Buede, *verification is the matching of [configuration items], components, sub-systems, and the system to corresponding requirements to ensure that each has been built right* (Buede 2009). This means that the verification process is instantiated as many times as necessary during the global development of the system. Because of the generic nature of a process, the verification process can be applied to any engineering element that has conducted to the definition and realization of the system elements and the system itself.

Facing the huge number of potential verification actions that may be generated by the normal approach, it is necessary to optimize the verification strategy. This strategy is based on the balance between what must be verified and constraints, such as time, cost, and feasibility of testing, which naturally limit the number of verification actions and the risks one accepts when excluding some verification actions.

Several approaches exist that may be used for defining the verification process. The International Council on Systems Engineering (INCOSE) dictates that two main steps are necessary for verification: planning and performing verification actions (INCOSE 2012). NASA has a slightly more detailed approach that includes five main steps: prepare verification, perform verification, analyze outcomes, produce a report, and capture work products (NASA December 2007, 1-360, p. 102). Any approach may be used, provided that it is appropriate to the scope of the system, the constraints of the project, includes the activities of the process listed below in some way, and is appropriately coordinated with other activities.

Generic inputs are baseline references of the submitted element. If the element is a system, inputs are the logical and physical architecture elements as described in a system design document, the design description of internal interfaces to the system and interfaces requirements external to the system, and by extension, the system requirements. **Generic outputs** define the verification plan that includes verification strategy, selected verification actions, verification procedures, verification tools, the verified element or system, verification reports, issue/trouble reports, and change requests on design.

Activities of the Process

To establish the verification strategy drafted in a verification plan (this activity is carried out concurrently to system definition activities), the following steps are necessary:

- Identify verification scope by listing as many characteristics or properties as possible that should be checked. The number of verification actions can be extremely high.
- Identify constraints according to their origin (technical feasibility, management constraints as cost, time, availability of verification means or qualified personnel, and contractual constraints that are critical to the mission) that limit potential verification actions.
- Define appropriate verification techniques to be applied, such as inspection, analysis, simulation, peer-review, testing, etc., based on the best step of the project to perform every verification action according to the given constraints.
- Consider a tradeoff of what should be verified (scope) taking into account all constraints or limits and deduce what can be verified; the selection of verification actions would be made according to the type of system, objectives of the project, acceptable risks, and constraints.
- Optimize the verification strategy by defining the most appropriate verification technique for every verification action while defining necessary verification means (tools, test-benches, personnel, location, and facilities) according to the selected verification technique.
- Schedule the execution of verification actions in the project steps or milestones and define the configuration of elements submitted to verification actions (this mainly involves testing on physical elements).

Performing verification actions includes the following tasks:

- Detail each verification action; in particular, note the expected results, the verification techniques to be applied, and the corresponding means required (equipment, resources, and qualified personnel).
- Acquire verification means used during system definition steps (qualified personnel, modeling tools, mocks-up, simulators, and facilities), and then those used during the integration step (qualified personnel, verification tools, measuring equipment, facilities, verification procedures, etc.).
- Carry out verification procedures at the right time, in the expected environment, with the expected means, tools, and techniques.

- Capture and record the results obtained when performing verification actions using verification procedures and means.

The obtained results must be analyzed and compared to the expected results so that the status may be recorded as either *compliant* or *non-compliant*. Systems engineering (SE) practitioners will likely need to generate verification reports, as well as potential issue/trouble reports, and change requests on design as necessary.

Controlling the process includes the following tasks:

- Update the verification plan according to the progress of the project; in particular, planned verification actions can be redefined because of unexpected events.
- Coordinate verification activities with the project manager: review the schedule and the acquisition of means, personnel, and resources. Coordinate with designers for issues/trouble/non-conformance reports and with the configuration manager for versions of the physical elements, design baselines, etc.

Artifacts and Ontology Elements

This process may create several artifacts such as:

- verification plans (contain the verification strategy)
- verification matrices (contain the verification action, submitted element, applied technique, step of execution, system block concerned, expected result, obtained result, etc.)
- verification procedures (describe verification actions to be performed, verification tools needed, the verification configuration, resources and personnel needed, the schedule, etc.)
- verification reports
- verification tools
- verified elements
- issue / non-conformance / trouble reports
- change requests to the design

This process utilizes the ontology elements displayed in Table 2 below.

Table 2. Main Ontology Elements as Handled within Verification. (SEBoK Original)

Element	Definition
	Attributes (examples)
Verification Action	A verification action describes what must be verified (the element as reference) on which element, the expected result, the verification technique to apply, on which level of decomposition.
	Identifier, name, description
Verification Procedure	A verification procedure groups a set of verification actions performed together (as a scenario of tests) in a gin verification configuration.
	Identifier, name, description, duration, unit of time
Verification Tool	A verification tool is a device or physical tool used to perform verification procedures (test bench, simulator, cap/stub, launcher, etc.).
	Identifier, name, description
Verification Configuration	A verification configuration groups all physical elements (aggregates and verification tools) necessary to perform a verification procedure.
	Identifier, name, description

Risk	An event having a probability of occurrence and a gravity degree on its consequence onto the system mission or on other characteristics (used for technical risk in engineering). A risk is the combination of vulnerability and of a danger or a threat.
Rationale	An argument that provides the justification for the selection of an engineering element.
	Identifier, name, description (rationale, reasons for defining a verification action, a verification procedure, for using a verification tool, etc.)

Methods and Techniques

There are several verification techniques to check that an element or a system conforms to its design references or its specified requirements. These techniques are almost the same as those used for validation, though the application of the techniques may differ slightly. In particular, the purposes are different; verification is used to detect faults/defects, whereas validation is used to provide evidence for the satisfaction of (system and/or stakeholder) requirements. Table 3 below provides descriptions of some techniques for verification.

Table 3. Verification Techniques. (SEBoK Original)

Verification Technique	Description
Inspection	Technique based on visual or dimensional examination of an element; the verification relies on the human senses or uses simple methods of measurement and handling. Inspection is generally non-destructive, and typically includes the use of sight, hearing, smell, touch, and taste, simple physical manipulation, mechanical and electrical gauging, and measurement. No stimuli (tests) are necessary. The technique is used to check properties or characteristics best determined by observation (e.g. paint color, weight, documentation, listing of code, etc.).
Analysis	Technique based on analytical evidence obtained without any intervention on the submitted element using mathematical or probabilistic calculation, logical reasoning (including the theory of predicates), modeling and/or simulation under defined conditions to show theoretical compliance. Mainly used where testing to realistic conditions cannot be achieved or is not cost-effective.
Analogy or Similarity	Technique based on evidence of similar elements to the submitted element or on experience feedback. It is absolutely necessary to show by prediction that the context is invariant that the outcomes are transposable (models, investigations, experience feedback, etc.). Similarity can only be used if the submitted element is similar in design, manufacture, and use; equivalent or more stringent verification actions were used for the similar element, and the intended operational environment is identical to or less rigorous than the similar element.
Demonstration	Technique used to demonstrate correct operation of the submitted element against operational and observable characteristics without using physical measurements (no or minimal instrumentation or test equipment). Demonstration is sometimes called 'field testing'. It generally consists of a set of tests selected by the supplier to show that the element response to stimuli is suitable or to show that operators can perform their assigned tasks when using the element. Observations are made and compared with predetermined/expected responses. Demonstration may be appropriate when requirements or specification are given in statistical terms (e.g. mean time to repair, average power consumption, etc.).
Test	Technique performed onto the submitted element by which functional, measurable characteristics, operability, supportability, or performance capability is quantitatively verified when subjected to controlled conditions that are real or simulated. Testing often uses special test equipment or instrumentation to obtain accurate quantitative data to be analyzed.
Sampling	Technique based on verification of characteristics using samples. The number, tolerance, and other characteristics must be specified to be in agreement with the experience feedback.

Practical Considerations

Key pitfalls and good practices related to this topic are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing System Verification are provided in Table 4.

Table 4. Major Pitfalls with System Verification (SEBoK Original)

Pitfall	Description
Confusion between verification and validation	Confusion between verification and validation causes developers to take the wrong reference/baseline to define verification and validation actions and/or to address the wrong level of granularity (detail level for verification, global level for validation).
No verification strategy	One overlooks verification actions because it is impossible to check every characteristic or property of all system elements and of the system in any combination of operational conditions and scenarios. A strategy (justified selection of verification actions against risks) must be established.
Save or spend time	Skip verification activity to save time.
Use only testing	Use only testing as a verification technique. Testing requires checking products and services only when they are implemented. Consider other techniques earlier during design; analysis and inspections are cost effective and allow discovering early potential errors, faults, or failures.
Stop verifications when funding is diminished	Stopping the performance of verification actions when budget and/or time are consumed. Prefer using criteria such as coverage rates to end verification activity.

Proven Practices

Some proven practices gathered from the references are provided in Table 5.

Table 5. Proven Practices with System Verification. (SEBoK Original)

Practice	Description
Start verifications early in the development	The earlier characteristics of an element are verified in the project, the easier the corrections are to do and the consequences on schedule and cost will be fewer.
Define criteria ending verifications	Carrying out verification actions without limits generates a risk of drift for costs and deadlines. Modifying and verifying in a non-stop cycle until arriving at a perfect system is the best way to never supply the system. Thus, it is necessary to set limits of cost, time, and a maximum number of modification loops back for each verification action type, ending criteria (percentages of success, error count detected, coverage rate obtained, etc.).
Involve design responsible with verification	Include the verification responsible in the designer team or include some designer onto the verification team.

System Transition

- Lead Authors:
- Scott Jackson and Brian Gallagher

-

As part of system deployment, on-site installation, check-out, integration, and testing must be carried out to ensure that the system is fit to be deployed into the field and/or put into an operational context. *Transfer* is the process that bridges the gap between qualification and use; it deals explicitly with the handoff from development to logistics, operations, maintenance, and support.

Definition & Purpose

There are many different approaches to transition or deployment, and many different views on what is included within transition. The SEBoK uses the ISO/IEC/IEEE 15288 definition of transition, as seen below (ISO/IEC/IEEE 15288 2015):

> *[The transition] process installs a verified system, together with relevant enabling systems, e.g., operating system, support system, operator training system, user training system, as defined in agreements. This process is used at each level in the system structure and in each stage to complete the criteria established for exiting the stage.*

Thinking in a linear fashion, the system is transitioned into operation and then would be used and maintained in the operational environment. However, there are other views on transition. For example, the NASA *Systems Engineering Handbook* states that transition can include delivery for end-use as well as delivery of components for integration (NASA 2007). Using this view, transition is the mechanism for moving system components from implementation activities into integration activities. The NASA discussion of transition also implies that transition can include sustainment activities:

> *The act of delivery or moving of a product from the location where the product has been implemented or integrated, as well as verified and validated, to a customer.*

Many systems are deployed using an iterative or evolutionary approach where operationally useful capabilities are developed and deployed incrementally. While these operationally useful capabilities are fully deployed and transitioned into operational use, transition of logistics, maintenance, and support may occur incrementally or be delayed until after the full system capability is delivered.

Process Approaches

Just as there are multiple views on the definition of transition and deployment, there are also several ways to divide the activities required for transition. For example, the NASA *Systems Engineering Handbook* definition of transition states: *This act can include packaging, handling, storing, moving, transporting, installing, and sustainment activities* (2007). However, the SEBoK includes the topic of *sustainment* as separate from transition; this is instead covered under the maintenance and logistics topics. The International Council on Systems Engineering (INCOSE) views the transition process as two-step: planning and performance. Though there are several processes for deployment and transition, most generally include the following activities:

- **Develop a Deployment/Transition Strategy** - Planning for transition activities would ideally begin early in the SE life cycle, though it is possible to conduct these activities concurrently with realization activities. Planning should generally include some consideration of the common lower-level activities of installation, checkout, integration, and testing. Such activities are crucial to demonstrate that the system and the interfaces with the operational environment can function as intended and meet the contractual system specifications. For these activities to be effectively managed and efficiently implemented, the criteria, responsibility, and procedures for carrying out these activities should be clearly established and agreed upon during the planning phase.
- **Develop Plans for Transitioning Systems** - or system capabilities into operational use and support. Transition plans for the system or incremental system capabilities should be consistent with the overall transition strategy and agreed to by relevant stakeholders. Planning for transition will often include establishing a strategy for support, which may include organic support infrastructures, contractor logistics support, or other sources (Bernard et al. 2005, 1-49). It can also include defining the levels of support to be established. The strategy is important because it drives most of the other transition planning activities, as well as product design considerations. Transition plans should include considerations for coordination with the following activities:
  - **Installation** - Installation generally refers to the activities required to physically instate the system; this will likely include connecting interfaces to other systems such as electrical, computer, or security systems, and may include software interfaces as well. Installation planning should generally document the complexity of the system, the range of environmental conditions expected in the operational environment, any interface specifications, and human factors requirements such as safety. When real-world conditions require changes in the installation requirements, these should be documented and discussed with the relevant stakeholders.
  - **Integration** - Though system integration activities will generally be performed prior to installation, there may be additional steps for integrating the system into its operational setting. Additionally, if the system is being delivered incrementally, there will likely be integration steps associated with the transition (for more information on integration, please see the System Realization knowledge area (KA)).
  - **Verification and Validation (V&V)** - At this stage, V&V for physical, electrical, and mechanical checks may be performed in order to verify that the system has been appropriately installed. Acceptance tests conducted after delivery may become part of this process (for additional information on V&V, please see the System Realization KA). There are several types of acceptance tests which may be used:
  - **On-site Acceptance Test (OSAT)** - This test includes any field acceptance testing and is performed only after the system has successfully been situated in the operational environment. It may consist of functional tests to demonstrate that the system is functioning and performing properly.
    - *Field Acceptance Test* - This test includes flight and sea acceptance tests; it is performed, if applicable, only after the system has successfully passed the OSAT. The purpose of field testing is to demonstrate that the system meets the performance specifications called for in the system specifications in the actual operating environment.
    - *Operational Test and Evaluation (OT&E)* - An OT&E consists of a test series designed to estimate the operational effectiveness of the system.

- *Evaluate the readiness of the system to transition into operations* - This is based upon the transition criteria identified in the transition plan. These criteria should support an objective evaluation of the system's readiness for transition. The integration, verification, and validation activities associated with transition may be used to gauge whether the system meets transition criteria.
- *Analyze the results of transition activities throughout and any necessary actions* - As a result of analysis, additional transition activities and actions may be required. The analysis may also identify areas for improvement in future transition activities.

Some common issues that require additional considerations and SE activities are the utilization or replacement of legacy systems. It is also common for an organization to continue testing into the early operational phase. The following activities support these circumstances:

- **System Run-In** - After the successful completion of the various acceptance tests, the system(s) will be handed over to the user or designated post-deployment support organization. The tested system(s) may have to be verified for a stated period (called the system run-in, normally for one to two years) for the adequacy of reliability and maintainability (R&M) and integrated logistics support (ILS) deliverables. R&M are vital system operational characteristics having a dominant impact upon the operational effectiveness, the economy of in-service maintenance support, and the life cycle cost (LCC).
- **Phasing-In/Phasing-Out** - The need for phasing-in will usually be identified during the system definition, when it is clear that the new system entails the replacement of an existing system(s) (for additional information, please see the System Definition KA). These activities should help to minimize disruption to operations and, at the same time, minimize the adverse effect on operational readiness. It is also important that the phasing-in of a new system and the phasing-out of an existing system occur in parallel with the systems activities of the system run-in to maximize resource utilization. Other aspects of phasing-in/phasing-out to be considered include:
  - Proper planning for the phasing out of an existing system (if necessary).
  - For multi-user or complex systems, phase-by-phase introduction of the system according to levels of command, formation hierarchy, etc.
  - Minimum disruption to the current operations of the users.
  - Establishment of a feedback system from users on problems encountered in operation, etc.
  - Disposal process including handling of hazardous items, cost of disposal, approval etc.

Applicable Methods & Tools

A system may have to undergo reliability demonstration testing (RDT) to ensure that it meets its contractual R&M guarantees. RDT is conducted under actual field conditions, especially for large systems purchased in small quantity. During RDT, the system is operated in the field within stated test duration and all field data are systematically recorded. At the end of the test period, analysis of the RDT data is performed. Data analysis should facilitate determination of system reliability. One possible output of this analysis is shown in Figure 1 below.

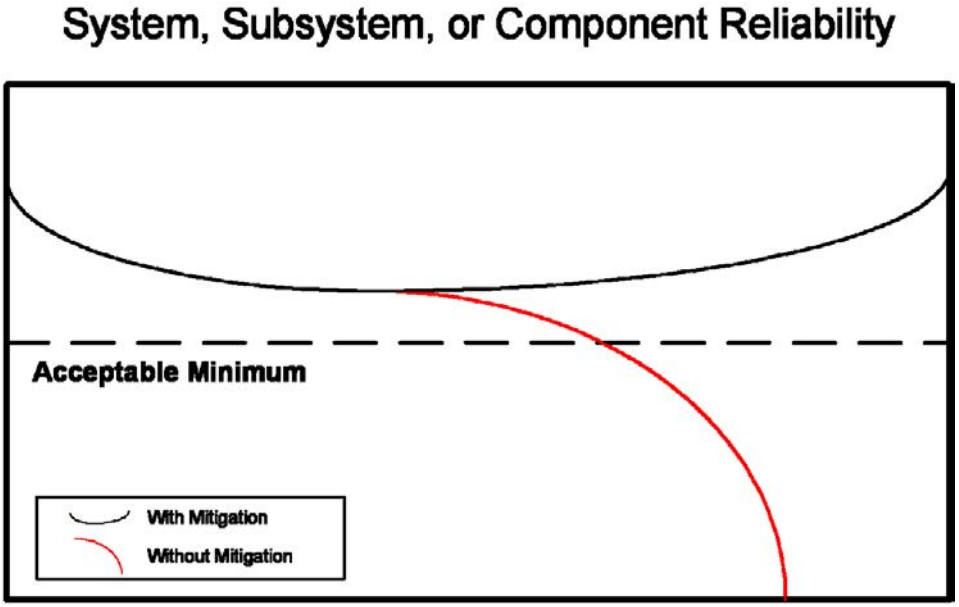

Figure 1. Notional Reliability Analysis. (SEBoK Original)

System Validation

- Lead Author:
- Alan Faisandier
- Contributing Author:
- Rick Adcock

-

System Validation is a set of actions used to check the compliance of any element (a system element, a system, a document, a service, a task, a system requirement, etc.) with its purpose and functions. These actions are planned and carried out throughout the life cycle of the system. Validation is a generic term that needs to be instantiated within the context it occurs. When understood as a process, validation is a transverse activity to every life cycle stage of the system. Particularly during the development cycle of the system, the validation process is performed in parallel with the system definition and system realization processes and applies to any activity and product resulting from this activity. The validation process is not limited to a phase at the end of system development, but generally occurs at the end of a set of life cycle tasks or activities, and always at the end of each milestone of a development project. It may be performed on an iterative basis on every produced engineering element during development and may begin with the validation of the expressed stakeholder needs and requirements. When the validation process is applied to the system when completely integrated, it is often called *final validation*. It is important to remember that while system validation is separate from verification, the activities are complementary and intended to be performed in conjunction.

Definition and Purpose

Validation is the confirmation, through the provision of objective evidence, that the requirements for a specific intended use or application have been fulfilled. With a note added in ISO 9000:2005: *validation is the set of activities that ensure and provide confidence that a system is able to accomplish its intended use, goals, and objectives (i.e., meet stakeholder requirements) in the intended operational environment* (ISO 2005).

The purpose of validation, as a generic action, is to establish the compliance of any activity output as compared to inputs of the activity. It is used to provide information and evidence that the transformation of inputs produced the expected and *right* result. Validation is based on tangible evidence; i.e., it is based on information whose veracity can be demonstrated by factual results obtained from techniques or methods such as inspection, measurement, test, analysis, calculation, etc. Thus, to validate a system (product, service, or enterprise) consists of demonstrating that it satisfies its system requirements and eventually the stakeholder's requirements depending on contractual practices. From a global standpoint, the purpose of validating a system is to acquire confidence in the system's ability to achieve its intended mission, or use, under specific operational conditions.

Principles

Concept of Validation Action

Why Validate?

The primary goal of systems engineering (SE) is to develop a solution that meets the needs and requirements of stakeholders. Validation is the process by which engineers ensure that the system will meet these needs and requirements.

A **validation action** is defined and then performed (see Figure 1, below).

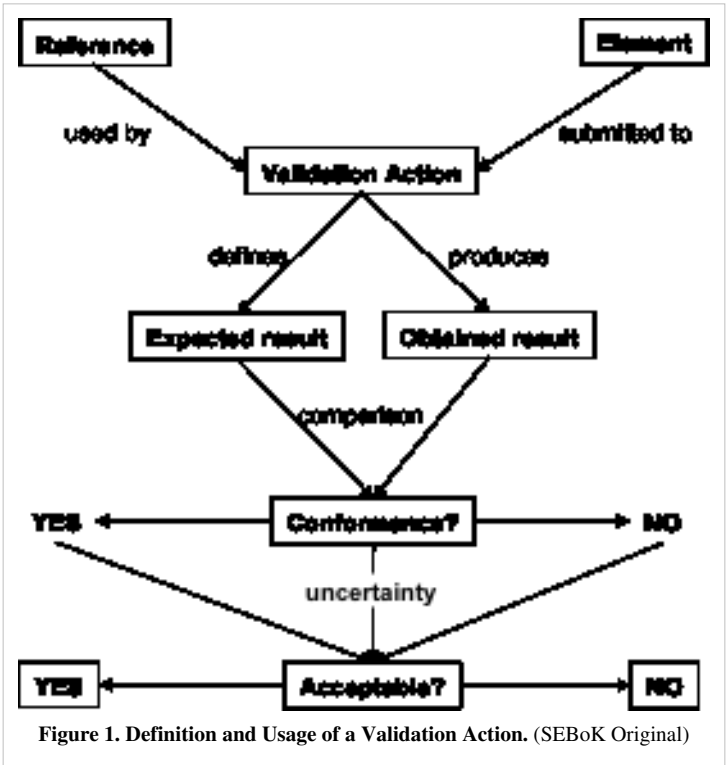

Figure 1. Definition and Usage of a Validation Action. (SEBoK Original)

A validation action applied to an engineering element includes the following:

- Identification of the element on which the validation action will be performed.
- Identification of the reference that defines the expected result of the validation action.

Performing the validation action includes the following:

- Obtaining a result by performing the validation action onto the submitted element.
- Comparing the obtained result with the expected result.
- Deducing the degree of compliance of the element.
- Deciding on the acceptability of this compliance, because sometimes the result of the comparison may require a value judgment to decide whether to accept the obtained result as compared to the relevance of the context of use.

Note: If there is uncertainty about compliance, the cause could come from ambiguity in the requirements.

What to Validate?

Any engineering element can be validated using a specific reference for comparison, such as stakeholder requirements, system requirements, functions, system elements, documents, etc. Examples are provided in Table 1 below:

Table 1. Examples of Validated Items (SEBoK Original)

Items	Explanation for Validation
Document	To validate a document is to make sure its content is compliant with the inputs of the task that produced the document.
Stakeholder Requirement and System Requirement	To validate a stakeholder requirement is to make sure its content is justified and relevant to stakeholders' expectations, complete and expressed in the language of the customer or end user. To validate a system requirement is to make sure its content translates correctly and/or accurately a stakeholder requirement to the language of the supplier.
Design	To validate the design of a system (logical and physical architectures) is to demonstrate that it satisfies its system requirements.
System	To validate a system (product, service, or enterprise) is to demonstrate that the product, service, or enterprise satisfies its system requirements and/or its stakeholder requirements.
Activity	To validate an activity or a task is to make sure its outputs are compliant with its inputs.
Process	To validate a process is to make sure its outcomes are compliant with its purpose.

Validation versus Verification

The Verification versus Validation section of the System Verification article gives fundamental differences between the two concepts and associated processes. The Table 2 provides information to help understand these differences.

Table 2. Verification and Validation Differences (may vary with context). (SEBoK Original)

Point of View	Verification	Validation
Purpose of the Activity	Detect, identify faults/defects (supplier oriented)	Acquire confidence (end user oriented)
Idea behind the Term	Based on truth (objective/unbiased)	Based on value judgement (more subjective)
Level of Concern	Detail and local	Global in the context of use
Vision	Glass box (how it runs inside)	Black box (application of inputs provides the expected effect)
Basic Method	Fine-tooth comb	Traceability matrix
System (Product, Service, Enterprise)	"Done Right" (respects the state of the art); focus on (physical) characteristics	"Does Right" (produces the expected effect); focus on services, functions
Baseline Reference for Comparison (Product, Service, Enterprise)	System design	System requirements (and stakeholder requirements)
Order of Performance	First	Second
Organization of Activity	Verification actions are defined and/or performed by development/designer team	Validation actions are defined and/or performed by experts and external members to development/designer team

Validation, Final Validation, and Operational Validation

System validation concerns the global system seen as a whole and is based on the totality of requirements (system requirements, stakeholders' requirements, etc.), but it is obtained gradually throughout the development stage in three non-exclusive ways:

- accumulating the results of verification actions and validation actions provided by the application of corresponding processes to every engineering element;
- performing final validation actions to the complete, integrated system in an industrial environment (as close as possible to the operational environment); and
- performing operational validation actions on the complete system in its operational environment (context of use).

Verification and Validation Level per Level

It is impossible to carry out only a single global validation on a complete, integrated complex system. The sources of faults/defects could be important, and it would be impossible to determine the causes of non-conformance manifested during this global check. Generally, the system-of-interest (SoI) has been decomposed during design in a set of layers of systems. Thus, every system and system element is verified, validated, and possibly corrected before being integrated into the parent system of the higher level, as shown in Figure 2.

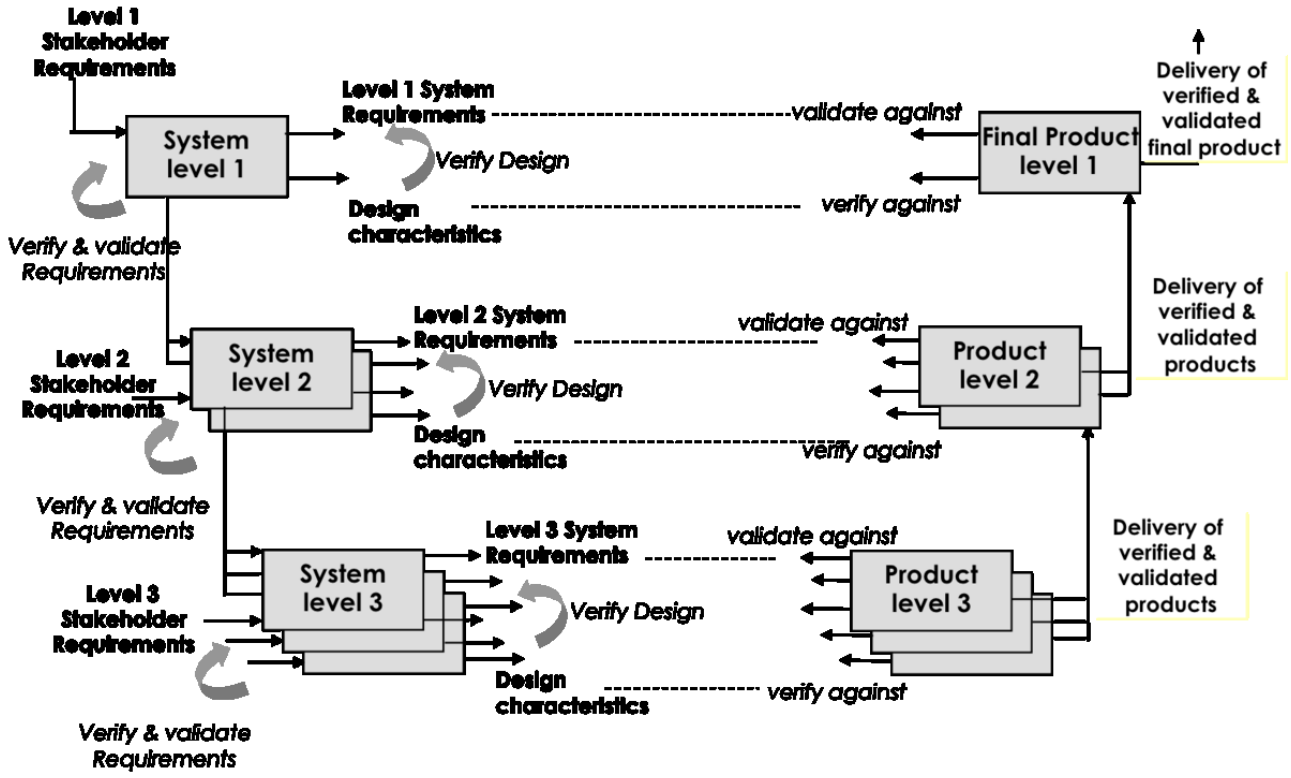

Figure 2. Verification and Validation Level Per Level. (SEBoK Original)

As necessary, systems and system elements are partially integrated in subsets in order to limit the number of properties to be verified within a single step. For each level, it is necessary to perform a set of final validation actions to ensure that features stated at preceding levels are not damaged. Moreover, a compliant result obtained in a given environment can turn into a non-compliant result if the environment changes. Thus, as long as the system is not completely integrated and/or doesn't operate in the real operational environment, no result should be regarded as definitive.

Verification Actions and Validation Actions Inside and Transverse to Levels

Inside each level of system decomposition, verification actions and validation actions are performed during system definition and system realization. This is represented in Figure 3 for the upper levels, and in Figure 4 for the lower levels. Stakeholder requirements definition and operational validation make the link between the two levels of the system decomposition.

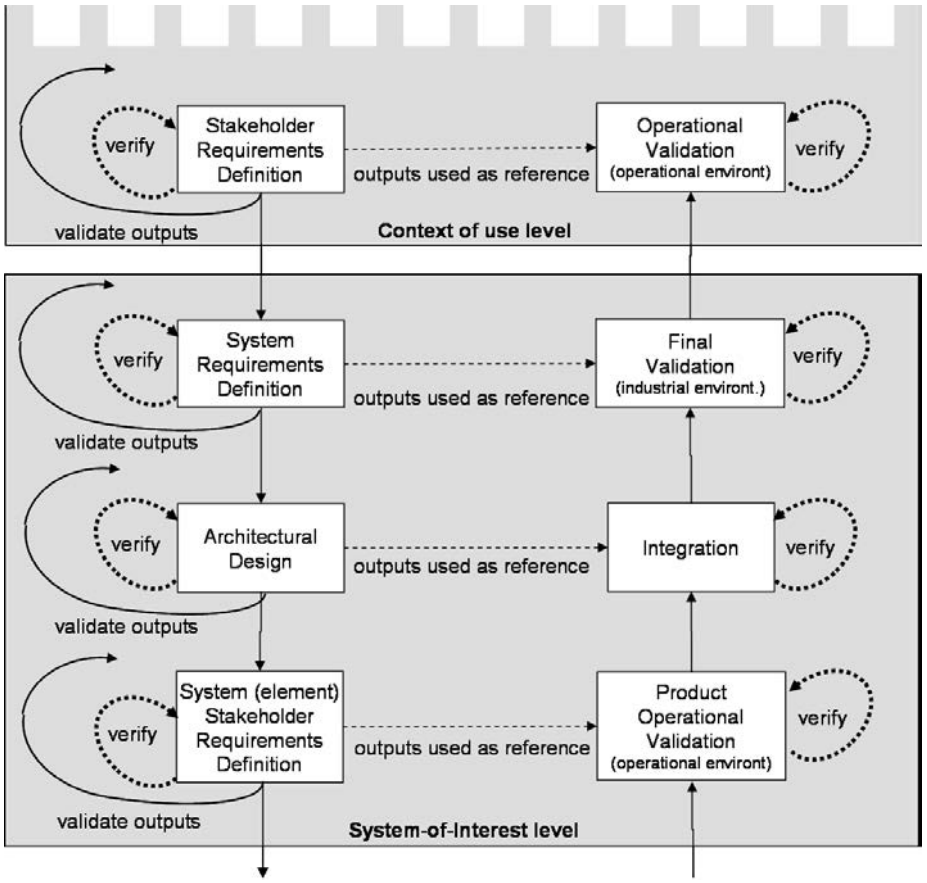

Figure 3. Verification and Validation Actions in Upper Levels of System Decomposition. (SEBoK Original)

Operational validation of system element requirements and products makes the link between the two lower levels of the decomposition. See Figure 4 below.

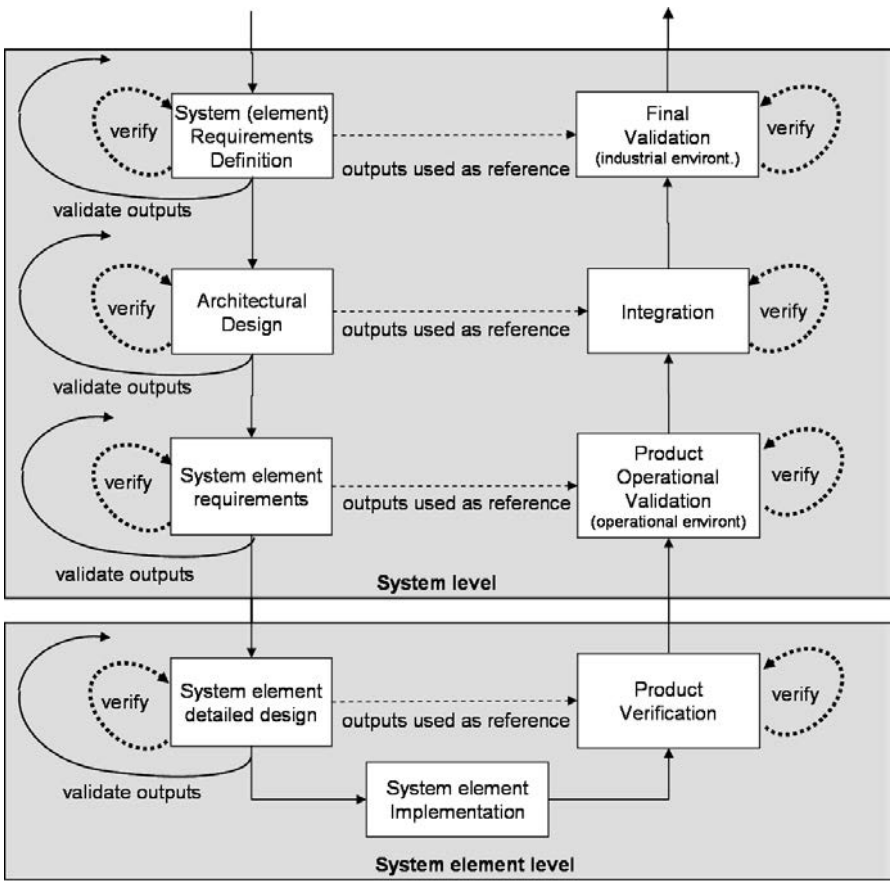

Figure 4. Verification and Validation Actions in Lower Levels of System Decomposition. (SEBoK Original)

Note: The last level of system decomposition is dedicated to the realization of system elements and the vocabulary and number of activities may be different from what is seen in Figure 4.

Verification and Validation Strategy

The difference between verification and validation is especially useful for elaborating on the integration strategy, the verification strategy, and the validation strategy. In fact, the efficiency of system realization is gained by optimizing the three strategies together to form what is often called the verification and validation strategy. This optimization consists of defining and performing the minimum number of verification and validation actions but detecting the maximum number of errors/faults/defects and achieving the maximum level of confidence in the system. The optimization takes into account the risks potentially generated if some verification actions or validation actions are excluded.

Process Approach

Purpose and Principles of the Approach

The purpose of the validation process is to provide objective evidence that the services provided by a system in use comply with stakeholder requirements and achieve its intended use in its intended operational environment (ISO/IEC/IEEE 15288 2015). The validation process performs a comparative assessment and confirms that the stakeholder requirements are correctly defined. Where variance is identified, it is recorded to guide future corrective actions. System validation is ratified by stakeholders (ISO/IEC/IEEE 15288 2015).

The validation process demonstrates that the realized end product satisfies its stakeholders' (customers' or other interested parties') expectations within the intended operational environments with validation performed by anticipated operators and/or users (NASA 2007, 1-360). Each system element, system, and the complete SoI are compared against their own applicable requirements (system requirements and stakeholder requirements). This means that the validation process is instantiated as many times as necessary during the global development of the system.

In order to ensure that validation is feasible, the implementation of requirements must be verifiable onto a defined element. It is essential to ensure that requirements are properly written, i.e., quantifiable, measurable, unambiguous, etc. In addition, verification/validation requirements are often written in conjunction with stakeholder and system requirements and provide a method for demonstrating the implementation of each system requirement or stakeholder requirement.

Generic inputs are references of requirements applicable to the submitted element. If the element is a system, inputs are system requirements and stakeholder requirements.

Generic outputs are the validation plan that includes validation strategy, selected validation actions, validation procedures, validation tools, validated elements or systems, validation reports, issue/trouble reports, and change requests on requirements or on the system.

Activities of the Process

Major activities and tasks performed during this process include the following:

- Establish a validation strategy (often drafted in a validation plan). This activity is carried out concurrently to system definition activities:
  - Identify the validation scope that is represented by (system and/or stakeholder) requirements; normally, every requirement should be checked as the number of validation actions can be high.
  - Identify constraints according to their origin (technical feasibility, management constraints as cost, time, availability of validation means or qualified personnel, and contractual constraints that are critical to the mission) that limit or increase potential validation actions.
  - Define appropriate verification/validation techniques to be applied, such as inspection, analysis, simulation, review, testing, etc., depending on the best step of the project to perform every validation action according to constraints.
  - Consider a trade-off of what should be validated (scope) while taking into account all constraints or limits and deduce what can be validated objectively; selection of validation actions would be made according to the type of system, objectives of the project, acceptable risks, and constraints.
  - Optimize the validation strategy to define the most appropriate validation technique for every validation action, define necessary validation means (tools, test-benches, personnel, location, and facilities) according to the selected validation technique, schedule the execution of validation actions in the project steps or milestones, and define the configuration of elements submitted to validation actions (this is primarily about testing on physical elements).
- Perform validation actions, including the following tasks:
  - Detail each validation action. In particular, note the expected results, the validation technique to be applied, and the corresponding means necessary (equipment, resources, and qualified personnel).
  - Acquire validation means used during the system definition steps (qualified personnel, modeling tools, mocks-up, simulators, and facilities), then those means used during integration and final and operational steps (qualified personnel, validation tools, measuring equipment, facilities, validation procedures, etc.).
  - Carry out validation procedures at the right time, in the expected environment, with the expected means, tools, and techniques.

    - Capture and record results obtained when performing validation actions using validation procedures and means.
- Analyze the obtained results and compare them to the expected results. Decide if they comply acceptably. Record whether the decision and status are compliant or not, and generate validation reports and potential issue/trouble reports, as well as change requests on (system or stakeholder) requirements as necessary.
- Control the process using following tasks:
    - Update the validation plan according to the progress of the project; in particular, planned validation actions can be redefined because of unexpected events.
    - Coordinate validation activities with the project manager regarding the schedule, acquisition of means, personnel, and resources. Coordinate with the designers for issue/trouble/non-conformance reports. Coordinate with the configuration manager for versions of physical elements, design baselines, etc.

Artifacts and Ontology Elements

This process may create several artifacts, such as:

- a validation plan (contains the validation strategy)
- a validation matrix (contains for each validation action, submitted element, applied technique, step of execution, system block concerned, expected result, obtained result, etc.)
- validation procedures (describe the validation actions to be performed, the validation tools needed, the validation configuration, resources, personnel, schedule, etc.)
- validation reports
- validation tools
- the validated element
- issue, non-conformance, and trouble reports
- change requests on requirements, products, services, and enterprises

This process utilizes the ontology elements of Table 3.

Table 3. Main Ontology Elements as Handled within Validation. (SEBoK Original)

Element	Definition
	Attributes (examples)
Validation Action	A validation action describes what must be validated (the element as reference), on which element, the expected result, the verification technique to apply, on which level of decomposition.
	Identifier, name, description
Validation Procedure	A validation procedure groups a set of validation actions performed together (as a scenario of tests) in a given validation configuration.
	Identifier, name, description, duration, unit of time
Validation Tool	A validation tool is a device or physical tool used to perform validation procedures (test bench, simulator, cap/stub, launcher, etc.).
	Identifier, name, description
Validation Configuration	A validation configuration groups the physical elements necessary to perform a validation procedure.
	Identifier, name, description

Risk	An event having a probability of occurrence and a gravity degree on its consequence onto the system mission or on other characteristics (used for technical risk engineering).
	Identifier, name, description, status
Rationale	An argument that provides the justification for the selection of an engineering element.
	Identifier, name, description (rationale, reasons for defining a validation action, a validation procedure, for using a validation tool, etc.)

Methods and Techniques

The validation techniques are the same as those used for verification, but their purposes are different; verification is used to detect faults/defects, whereas validation is used to prove the satisfaction of (system and/or stakeholder) requirements.

The **validation traceability matrix** is introduced in the stakeholder requirements definition topic. It may also be extended and used to record data, such as a validation actions list, selected validation techniques to validate implementation of every engineering element (stakeholder and system requirements in particular), expected results, and obtained results when validation actions have been performed. The use of such a matrix enables the development team to ensure that selected stakeholder and system requirements have been checked, or to evaluate the percentage of validation actions completed.

Practical Considerations

Key pitfalls and good practices related to system validation are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in planning and performing system validation are provided in Table 4.

Table 4. Major Pitfalls with System Validation. (SEBoK Original)

Pitfall	Description
Start validation at the end of the project	A common mistake is to wait until the system has been entirely integrated and tested (design is qualified) to perform any sort of validation. Validation should occur as early as possible in the [product] life cycle (Martin 1997).
Use only testing	Use only testing as a validation technique. Testing requires checking products and services only when they are implemented. Consider other techniques earlier during design; analysis and inspections are cost effective and allow discovering early potential errors, faults, or failures.
Stop validation when funding is diminished	Stop the performance of validation actions when budget and/or time are consumed. Prefer using criteria such as coverage rates to end validation activity.

Proven Practices

Some good practices gathered from the references are provided in Table 5.

Table 5. Proven Practices with System Validation. (SEBoK Original)

Practice	Description
Start Validation Plan Early	It is recommended to start the drafting of the validation plan as soon as the first requirements applicable to the system are known. If the writer of the requirements immediately puts the question to know how to validate whether the future system will answer the requirements, it is possible to: • detect the unverifiable requirements • anticipate, estimate cost, and start the design of validation means (as needed) such as test-benches, simulators • avoid cost overruns and schedule slippages
Verifiable Requirements	According to Buede, a requirement is verifiable if a "finite, cost-effective process has been defined to check that the requirement has been attained." (Buede 2009) Generally, this means that each requirement should be quantitative, measurable, unambiguous, understandable, and testable. It is generally much easier and more cost-effective to ensure that requirements meet these criteria while they are being written. Requirement adjustments made after implementation and/or integration are generally much more costly and may have wide-reaching redesign implications. There are several resources which provide guidance on creating appropriate requirements - see the system definition knowledge area, stakeholder requirements, and system requirements topics for additional information.
Document Validation Actions	It is important to document both the validation actions performed and the results obtained. This provides accountability regarding the extent to which system, system elements, and subsystems fulfill system requirements and stakeholders' requirements. These data can be used to investigate why the system, system elements, or subsystems do not match the requirements and to detect potential faults/defects. When requirements are met, these data may be reported to organization parties. For example, in a safety critical system, it may be necessary to report the results of safety demonstration to a certification organization. Validation results may be reported to the acquirer for contractual aspects or to internal company for business purpose.
Involve Users with Validation	Validation will often involve going back directly to the users to have them perform some sort of acceptance test under their own local conditions.
Involve	Often the end users and other relevant stakeholders are involved in the validation process.

The following are elements that should be considered when practicing any of the activities discussed as a part of system realization:

- Confusing verification and validation is a common issue. Validation demonstrates that the product, service, and/or enterprise as provided, fulfills its intended use, whereas verification addresses whether a local work product properly reflects its specified requirements. Validation actions use the same techniques as the verification actions (e.g., test, analysis, inspection, demonstration, or simulation).
- State who the witnesses will be (for the purpose of collecting the evidence of success), what general steps will be followed, and what special resources are needed, such as instrumentation, special test equipment or facilities, simulators, specific data gathering, or rigorous analysis of demonstration results.
- Identify the test facility, test equipment, any unique resource needs and environmental conditions, required qualifications and test personnel, general steps that will be followed, specific data to be collected, criteria for repeatability of collected data, and methods for analyzing the results.

System Operation

- Lead Authors:
- Scott Jackson and Brian Gallagher
- Contributing Author:
- Leopoldo deCardenas

-

The role of systems engineering (SE) during the operation of a system consists of ensuring that the system maintains key mission and business functions and is operationally effective. The systems engineer is one of the stakeholders who ensures that maintenance actions and other major changes are performed according to the long-term vision of the system. Both the maintenance actions and any implemented changes must meet the evolving needs of owning and operating stakeholders consistent with the documented and approved architecture. SE considerations will also include the eventual decommissioning or disposal of the system so that the disposal occurs according to disposal/retirement plans. Those plans must account for and be compliant with relevant laws and regulations (for additional information on disposal or retirement, please see the Product and Service Life Management knowledge area (KA)). When the system-of-interest (SoI) replaces an existing or legacy system, it may be necessary to manage the migration between systems such that stakeholders do not experience a breakdown in services (INCOSE 2012).

Definition & Purpose

This process assigns personnel to operate the system and monitors the services and operator-system performance. In order to sustain services, it identifies and analyzes operational problems in relation to agreements, stakeholder requirements, and organizational constraints (ISO/IEC/IEEE 2015).

The concept of operations (ConOps) establishes the foundation for initial design specifications according to the long-term vision. It is also possible that pre-planned program improvements (P3I) had been generated based on expected evolving requirements. Throughout the systems life cycle, the operation of the system requires the systems engineer to be an active participant in reviews, change management and integrated master schedule activities to ensure the system operations continue to meet the evolving needs of stakeholders, and are consistent with the architecture through the eventual decommissioning or disposal of the system. In the event of decommissioning, a systems engineer must ensure disposal/retirement plans are compliant with relevant laws and regulations (for additional information on disposal or retirement, see the Product and Service Life Management KA).

Two additional areas are of interest to the systems engineer during system operation require special attention. First, it may be determined that a system is at the end of its life cycle, but the cost of replacing the system with a completely new design is too expensive. In this case, there will be intense engineering activities for service life extension program (SLEP). The SLEP solution will take into account obsolescence issues, diminishing manufacturing sources and material shortages (DMSMS), and changes in ConOps. Secondly, in the event that a new SoI is designed and produced as a complete replacement for an existing or legacy system, it will be necessary to manage the migration between systems such that stakeholders do not experience a breakdown in services (INCOSE 2012).

Process Approaches

During the operational phase, SE activities ensure the system maintains certain operational attributes and usefulness throughout its expected life span. Maintaining operational effectiveness consists of evaluating certain operationally relevant attributes and trends, taking actions to prevent degradation of performance, evolving the system to meet changing mission or business needs (see the Product and Service Life Management KA), and eventually decommissioning the system and disposing of its components. During operation, data would be collected to evaluate the system and determine if changes should be made. It is important to include the process for data collection during

operations when considering design and ConOps. In some cases, data may be collected by sensors and reported autonomously. In other cases, operators will identify and report on performance during operations. The systems engineer needs to understand how all data will be collected and presented for further analysis. The systems engineer will be involved in analysis of this data in several areas, including the following:

- Updating training and development of new training as required for operational and support personnel. Training is generally developed early with system design and production and executed during integration and operations. Determination of training updates or changes will be based on evaluation of the operational and support personnel.
- Evaluation of operational effectiveness. Early in the planning phases of a new system or capability, measures of operational effectiveness are established based on mission and business goals. These measures are important during system operation. These attributes are unique for each system and represent characteristics describing the usefulness of the system as defined and agreed to by system stakeholders. Systems engineers monitor and analyze these measurements and recommend actions.
- Failure reporting and corrective actions (FRACA) activities will involve the collection and analysis of data during operations. FRACA data will provide trends involving failures that may require design or component changes. Some failures may also result in safety issues requiring operational modifications until the offending elements under analysis can be corrected. If components or systems must be returned to maintenance facilities for corrective repairs, there will be operational and business impacts due to increased unavailability and unplanned transportation cost.

Applicable Methods & Tools

Operations manuals generally provide operators the steps and activities required to run the system.

Training and Certification

Adequate training must be provided for the operators who are required to operate the system. There are many objectives of training:

- Provide initial training for all operators in order to equip them with the skill and knowledge to operate the system. Ideally, this process will begin prior to system transition and will facilitate delivery of the system. It is important to define the certification standards and required training materials up front (for more information on material supply, please see Logistics).
- Provide continuation training to ensure currency of knowledge.
- Monitor the qualification/certification of the operators to ensure that all personnel operating the system meet the minimum skill requirements and that their currency remains valid.
- Monitor and evaluate the job performance to determine the adequacy of the training program.

Practical Considerations

The operation process sustains system services by assigning trained personnel to operate the system, as well as by monitoring operator-system performance and monitoring the system performance. In order to sustain services, the operation process identifies and analyzes operational problems in relation to agreements, stakeholder needs and requirements, and organizational constraints. When the system replaces an existing system, it may be necessary to manage the migration between systems such that persistent stakeholders do not experience a breakdown in services.

Results of a successful implementation of the operation process include:

- Definition and refinement of an operation strategy along the way
- Delivery of services that meet stakeholder requirements
- Satisfactory completion of approved, corrective action requests
- Continued stakeholder satisfaction

Outputs of the operation process include:

- Operational strategy, including staffing and sustainment of enabling systems and materials
- System performance reports (statistics, usage data, and operational cost data)
- System trouble/anomaly reports with recommendations for appropriate action
- Operational availability constraints to influence future design and specification of similar systems or reused system elements

Activities of the operation process include:

- Providing operator training to sustain a pool of operators
- Tracking system performance and accounting for operational availability
- Performing operational analysis
- Managing operational support logistics
- Documenting system status and actions taken
- Reporting malfunctions and recommendations for improvement

-

System Maintenance planning begins early in the acquisition process with development of a maintenance concept. Maintenance planning is conducted to evolve and establish requirements and tasks to be accomplished for achieving, restoring, and maintaining operational capability for the life of the system. For a system to be sustained throughout its system life cycle, the maintenance process has to be executed concurrently with the operations process (ISO/IEC/IEEE 15288 2015, Clause 6.4.9).

Topics

Each part of the SEBoK is divided into knowledge areas (KAs), which are groupings of information with a related theme. The KAs in turn are divided into topics. This KA contains the following topics:

- Logistics
- Service Life Management
- Service Life Extension
- Capability Updates, Upgrades, and Modernization
- System Disposal and Retirement

See the article Matrix of Implementation Examples for a mapping of case studies and vignettes included in Part 7 to topics covered in Part 3.

Overview

The initial requirements for maintenance have to be defined during the stakeholder needs definition process (Clause 6.4.1) (ISO/IEC/IEEE 15288 2015) and continue to evolve during the development and operation of the system. Considerations include:

- Maximizing system availability to meet the operational requirements. This has to take into account the designed-in reliability and maintainability of the system and resources available.
- Preserving system operating potential through proper planning of system scheduled maintenance. This requires a reliability-centered maintenance strategy that incorporates preventive maintenance in order to preempt failures, thereby extending the mean time between corrective maintenance, as well as enhancing the availability of the

system.
- Segmenting maintenance activities for potential outsourcing of non-critical activities to approved maintenance subcontractors as to optimize scarce technical manpower resources and maintenance/repair turn-around times.
- Harnessing IT technology for maintenance management. This involves rigorous and systematic capturing and tracking of operating and maintenance activities to facilitate analysis and planning.

Maintenance management is concerned with the development and review of maintenance plans, as well as securing and coordinating resources, such as budget, service parts provisioning, and management of supporting tasks (e.g., contract administration, engineering support, and quality assurance). Maintenance planning relies on level of repair analysis (LORA) as a function of the system acquisition process. Initial planning addresses actions and support necessary to ensure a minimum life cycle cost (LCC).

Process Approaches

The purpose of the maintenance process is to sustain the capability of a system to provide a service. This process monitors the system's capability to deliver services, records problems for analysis, takes corrective, adaptive, perfective, and preventive actions, and confirms restored capability. As a result of the successful implementation of the maintenance process:

- a maintenance strategy is developed
- maintenance constraints are provided as inputs to requirements
- replacement system elements are made available
- services meeting stakeholder requirements are sustained
- the need for corrective design changes is reported
- failure and lifetime data are recorded

The project should implement the following activities and tasks in accordance with applicable organization policies and procedures with respect to the maintenance process:

- scheduled servicing, such as daily inspection/checks, servicing, and cleaning
- unscheduled servicing (carrying out fault detection and isolation to the faulty replaceable unit and replacement of the failed unit)
- re-configuration of the system for different roles or functions
- scheduled servicing (higher level scheduled servicing but below depot level)
- unscheduled servicing (carrying out more complicated fault isolation to the faulty replaceable unit and replacement of the failed unit)
- minor modifications
- minor damage repairs
- major scheduled servicing (e.g., overhaul and corrosion treatment)
- major repairs (beyond normal removal and replacement tasks)

The maintenance plan specifies the scheduled servicing tasks and intervals (preventive maintenance) and the unscheduled servicing tasks (adaptive or corrective maintenance). Tasks in the maintenance plan are allocated to the various maintenance agencies. A maintenance allocation chart is developed to tag the maintenance tasks to the appropriate maintenance agencies. These include: in-service or in-house work centers, approved contractors, affiliated maintenance or repair facilities, original equipment manufacturer (OEMs), etc. The maintenance plan also establishes the requirements for the support resources.

Related activities such as resource planning, budgeting, performance monitoring, upgrades, longer term supportability, and sustenance also need to be managed. These activities are planned, managed, and executed over a longer time horizon and they concern the well-being of the system over the entire life cycle.

Proper maintenance of the system (including maintenance-free system designs) relies very much on the availability of support resources, such as support and test equipment (STE), technical data and documentation, personnel, spares, and facilities. These have to be factored in during the acquisition agreement process.

Training and Certification

Adequate training must be provided for the technical personnel maintaining the system. While initial training may have been provided during the deployment phase, additional personnel may need to be trained to cope with the increased number of systems being fielded, as well as to cater to staff turnover. Timely updates to training materials and trained personnel may be required as part of system upgrades and evolution. It is important to define the certification standards and contract for the training materials as part of the supply agreement.

Practical Considerations

The organization responsible for maintaining the system should have clear thresholds established to determine whether a change requested by end users, changes to correct latent defects, or changes required to fulfill the evolving mission are within the scope of a maintenance change or require a more formal project to step through the entire systems engineering life-cycle. Evaluation criteria to make such a decision could include cost, schedule, risk, or criticality characteristics.

-

There are several definitions for logistics within systems engineering (SE) and the definition used will determine what activities are considered part of logistics. The SEBoK defines logistics as the science of planning and implementing the acquisition and use of the resources necessary to sustain the operation of a system.

Overview

The ability to *sustain the operation of a system* is determined by the inherent supportability of the system (a function of design) and the processes used to sustain the functions and capabilities of the system in the context of the end user. Figure 1, below, shows a Defense Acquisition University (DAU) model of the SE aspects for consideration in logistics and logistics planning (DAU 2010).

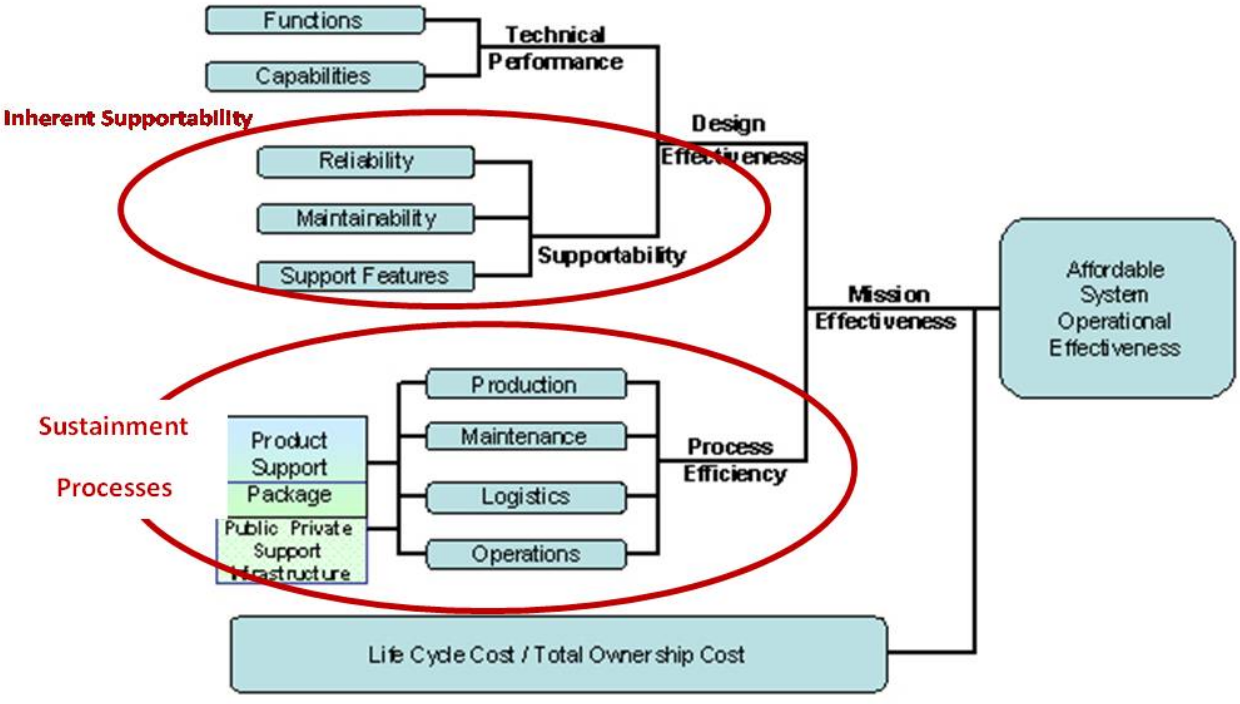

Figure 1. Affordable System Operational Effectiveness (DAU Guidebook 2010). Released by Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

Sustainment Planning

The focus of sustainment planning is to influence the inherent supportability of the system and to plan the sustainment capabilities and processes that will be used to sustain system operations.

Influence Inherent Supportability (Operational Suitability)

Sustainment influence requires an understanding of the concept of operations (ConOps), system missions, mission profiles, and system capabilities to understand the rationale behind functional and performance priorities. Understanding the rationale paves the way for decisions about necessary tradeoffs between system performance, availability, and life cycle cost (LCC), with impact on the cost effectiveness of system operation, maintenance, and logistics support. There is no single list of sustainment considerations or specific way of grouping them as they are highly inter-related. They include: compatibility, interoperability, transportability, reliability, maintainability, manpower, human factors, safety, natural environment effects (including occupational health, habitability; see Environmental Engineering); diagnostics & prognostics (including real-time maintenance data collection), and corrosion protection & mitigation. The following are key design considerations:

- **Architecture Considerations** - The focus on openness, modularity, scalability, and upgradeability is critical to implementing an incremental acquisition strategy. In addition, the architecture attributes that expand system flexibility and affordability can pay dividends later when obsolescence and end-of-life issues are resolved through a concerted technology refreshment strategy. Trade-offs are often required relative to the extent each attribute is used.
- **Reliability Considerations**: - Reliability is critical because it contributes to a system's effectiveness as well as its suitability in terms of logistics burden and the cost to fix failures. For each system, there is a level of basic reliability that must be achieved for the system to be considered useful. Reliability is also one of the most critical elements in determining the logistics infrastructure and footprint. Consequently, system reliability should be a primary focus during design (along with system technical performance, functions, and capabilities). The primary objective is to achieve the necessary probability of operational success and minimize the risk of failure within defined availability, cost, schedule, weight, power, and volume constraints. While performing such analyses, trade-offs should be conducted and dependencies should be explored with system maintainability and integrated with the supportability analysis that addresses support event frequency (i.e. reliability), event duration, and event cost. Such a focus will play a significant role in minimizing the necessary logistics footprint, while maximizing system availability.
- **Maintainability Considerations** - The design emphasis on maintainability is to reduce the maintenance burden and supply chain by reducing the time, personnel, tools, test equipment, training, facilities and cost to maintain the system. Maintainability engineering includes the activities, methods, and practices used to design minimal system maintenance requirements (designing out unnecessary and inefficient processes) and associated costs for preventive and corrective maintenance as well as servicing or calibration activities. Maintainability should be a designed-in capability and not an add-on option because good maintenance procedures cannot overcome poor system and equipment maintainability design. The primary objective is to reduce the time it takes for a properly trained maintainer to detect and isolate the failure (coverage and efficiency) and affect repair. Intrinsic factors contributing to maintainability are:
  - **Modularity** - Packaging of components such that they can be repaired via remove and replace action vs. on-board repair. Care should be taken not to *over modularize,* and trade-offs to evaluate replacement, transportation, and repair costs should be accomplished to determine the most cost-effective approach.
  - **Interoperability** - The compatibility of components with standard interface protocols to facilitate rapid repair and enhancement/upgrade through black box technology using common interfaces. Physical interfaces should be designed so that mating between components can only happen correctly.

    - **Physical accessibility** - The designed-in structural assurance that components which require more frequent monitoring, checkout, and maintenance can be easily accessed. This is especially important in low observable platforms. Maintenance points should be directly visible and accessible to maintainers, including access for corrosion inspection and mitigation.
    - Designs that require *minimum preventative maintenance* including corrosion prevention and mitigation. Emphasis should be on balancing the maintenance requirement over the life cycle with minimal user workload.
    - **Embedded training and testing** when it is determined to be the optimal solution from a total ownership cost (TOC) and materiel availability perspective.
    - **Human Systems Integration (HSI)** to optimize total system performance and minimize life-cycle costs by designing systems and incorporating technologies that (a) require minimal manpower, (b) provide effective training, (c) can be operated and maintained by users, (d) are suitable (habitable and safe with minimal environmental and occupational health hazards), and (e) are survivable (for both the user and the equipment).
- **Support Considerations** - Support features cannot be easily *added-on* after the design is established. Consequently, supportability should be a high priority early in the program's planning and integral to the system design and development process. Support features cut across reliability, maintainability, and the supply chain to facilitate detection, isolation, and timely repair/replacement of system anomalies. These include features for servicing and other activities necessary for operation and support including resources that contribute to the overall support of the system. Typical supportability features include diagnostics, prognostics (see CBM+ Guidebook), calibration requirements, many HSI issues (e.g. training, safety, HFE, occupational health, etc.), skill levels, documentation, maintenance data collection, compatibility, interoperability, transportability, handling (e.g., lift/hard/tie down points, etc.), packing requirements, facility requirements, accessibility, and other factors that contribute to an optimum environment for sustaining an operational system.

Planning Sustainment Processes

Process efficiency reflects how well the system can be produced, operated, serviced (including fueling) and maintained. It reflects the degree to which the logistics processes (including the supply chain), infrastructure, and footprint have been balanced to provide an agile, deployable, and operationally effective system.

Achieving process efficiency requires early and continuing emphasis on the various logistics support processes along with the design considerations. The continued emphasis is important because processes present opportunities for improving operational effectiveness even after the *design-in* window has passed via lean-six sigma, supply chain optimization, or other continuous process improvement (CPI) techniques.

Sustainment Analysis (Product Support Package)

The product support package documents the output of supportability analysis and includes details related to the following twelve elements (links below are to excerpts from (NATO RTO 2001):

- Product/information technology (IT) system/medical system support management (integrated life cycle sustainment planning)
    - product/IT system/medical system support strategies
    - life cycle sustainment planning
    - requirements management
    - total ownership costs (TOC)/life cycle costs (LCC) planning & management
    - Integration and management of product support activities
    - configuration management
    - production & distribution
    - energy, environmental, safety and health (EESH) management
    - policies & guidance

    - risk management
- Design Interface [1]
    - reliability
    - maintainability
    - supportability
    - affordability
    - configuration management
    - safety requirements
    - environmental and hazardous materials (HAZMAT) requirements
    - human systems integration (HSI)
    - calibration
    - anti-tamper
    - habitability
    - disposal
    - legal requirements
- Sustainment Engineering
    - failure reporting, analysis, and corrective action system (FRACAS)
    - value engineering
    - diminishing manufacturing sources and material shortages (DMSMS)
- Supply Support (materiel planning) [2]
- Maintenance Planning [3]
    - reliability centered maintenance (RCM)
    - maintenance concepts
    - levels of maintenance (level of repair analysis)
    - condition-based maintenance
    - prognostics & health management
- Support Equipment [4]
- Technical Data [5]
- Manpower & Personnel [6]
- Training & Training Support [7]
- Facilities & Infrastructure [8]
- Packaging, Handling, Storage, & Transportation [9]
- Computer Resources [10]

Sustainment Implementation

Once the system becomes operational, the results of sustainment planning efforts need to be implemented. SE supports the execution of the twelve integrated product support elements of a sustainment program that strives to ensure the system meets operational performance requirements in the most cost-effective manner over its total remaining life cycle, as illustrated in Figure 2.

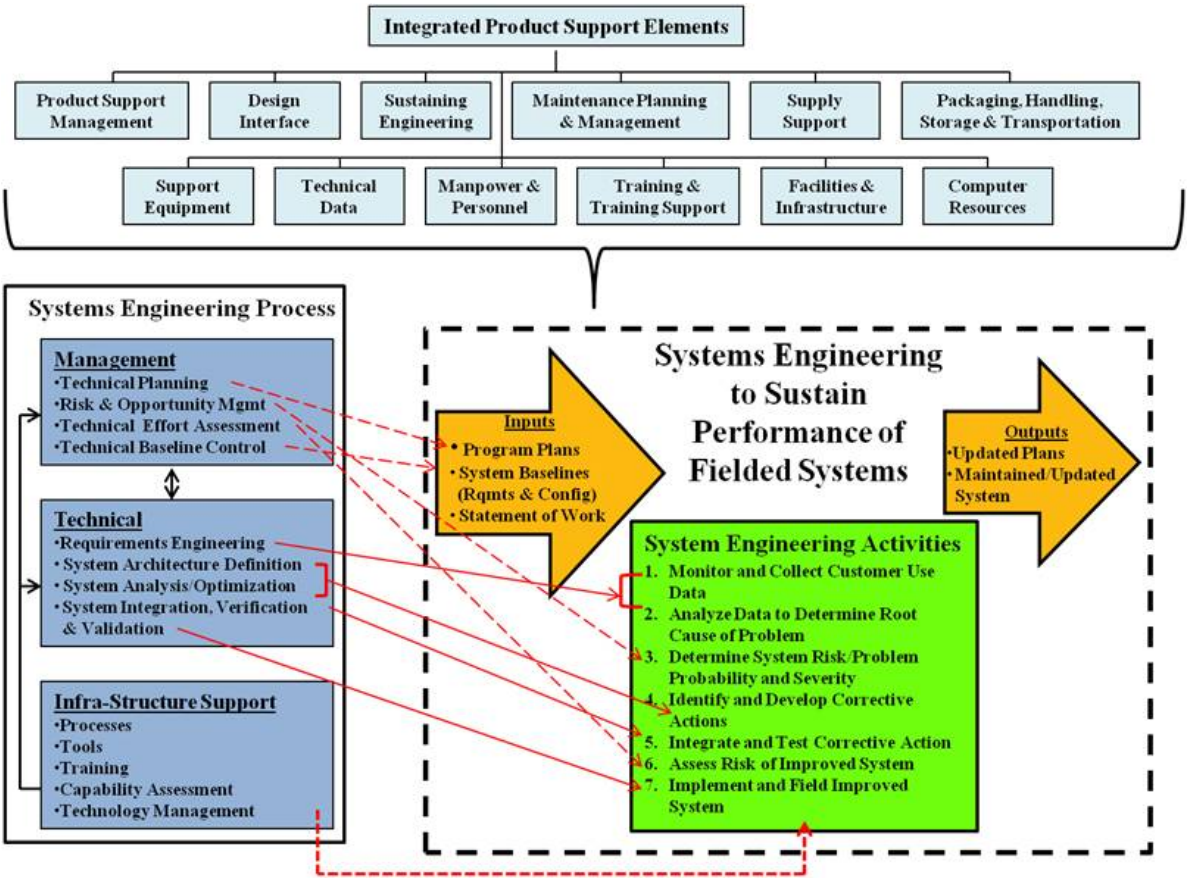

Figure 2. Sustainment Implementation Illustration (DAU Guidebook 2012). Released by Defense Acquisition University (DAU)/U.S. Department of Defense (DoD).

Once a system is put into use, SE is often required to correct problems that degrade continued use, and/or to add new capabilities to improve product performance in the current or a new environment. In the context of integrated product support, these SE activities correspond to the integrated product support (IPS) element *Sustaining Engineering*. Changes made to fielded systems to correct problems or increase performance should include any necessary adjustments to the IPS elements, and should consider the interrelationships and integration of the elements to maintain the effectiveness of the system's support strategy.

The degree of change required to the product support elements varies with the severity of the problem. Minor problems may require a simple adjustment to a maintenance procedure, a change of supplier, a training course modification or a change to a technical manual. In contrast, problems that require system or component redesign may require engineering change proposals and approvals, IPS element trade studies, business case analysis, and updates to the product support strategy. The focus is to correct problems that degrade continued use, regardless of the degree of severity.

Evolutionary systems provide a strategy for acquisition of mature technology; the system delivers capabilities incrementally, planning for future capability enhancements. A system of systems (SoS) perspective is required for these systems to synchronize the primary and sustainment systems.

Service Life Management

- Contributing Author:
- William Stiffler

-

Product and service life management deals with the overall life cycle planning and support of a system. The life of a product or service spans a considerably longer period of time than the time required to design and develop the system. Systems engineers need to understand and apply the principles of life management throughout the life cycle of the system. (See Life Cycle Models for a general discussion of life cycles.) Specifically, this article focuses on changes to a system after deployment, including extension, modernization, disposal, and retirement.

Overview

Product and service life management is also referred to as *system sustainment*. Sustainment involves the supportability of operational systems from the initial procurement to disposal. Sustainment is a key task for systems engineering that influences product and service performance and support costs for the entire life of the program.

Sustainment activities include: design for maintainability, application of built-in test, diagnostics, prognostics and other condition-based maintenance techniques, implementation of logistics footprint reduction strategies, identification of technology insertion opportunities, identification of operations and support cost reduction opportunities, and monitoring of key support metrics. Life cycle sustainment plans should be created for large, complex systems (DAU 2010). Product and service life management applies to both commercial systems (e.g. energy generation and distribution systems, information management systems, the Internet, and health industries) and government systems (e.g. defense systems, transportation systems, water-handling systems, and government services).

It is critical that the planning for system life management occur during the requirements phase of system development. (See System Requirements and System Definition). The requirements phase includes the analysis of life cycle cost alternatives, as well as gaining the understanding of how the system will be sustained and modified once it is operational.

The body of knowledge associated with product and service life management includes the following areas:

1. Service Life Extension - Systems engineers need to understand the principles of service life extension, the challenges that occur during system modifications, and issues involved with the disposal and retirement after a system has reached the end of its useful life.
2. Modernization and Upgrades - Managing service life extension uses the engineering change management process with an understanding of the design life constraints of the system. Modernizing existing legacy systems requires special attention and understanding of the legacy requirements and the importance of having a complete inventory of all the system interfaces and technical drawings.
3. Disposal and Retirement - Disposal and retirement of a product after reaching its useful life requires attention to environmental concerns, special handling of hazardous waste, and concurrent operation of a replacement system as the existing system is being retired.

Principles and Standards

The principles of product and service life management apply to different types of systems and domains. The type of system (commercial or government) should be used to select the correct body of knowledge and best practices that exist in different domains. For example, U.S. military systems would rely on sustainment references and best practices from the Department of Defense (DoD) (e.g., military services, Defense Acquisition University (DAU), etc.) and military standardization bodies (e.g., the American Institute of Aeronautics and Astronautics (AIAA), the Society of Automotive Engineers (SAE), the Society of Logistics Engineers (SOLE), the Open Geospatial Consortium (OGC), etc.).

Commercial aviation, power distribution, transportation, water-handling systems, the Internet, and health industries would rely on system life management references and best practices from a combination of government agencies, local municipalities, and commercial standardization bodies and associations (e.g., in the U.S.- the Department of Transportation (DOT), State of Michigan, International Organization for Standardization (ISO), Institute of Electrical and Electronics Engineers (IEEE), International Council on Systems Engineering (INCOSE), etc.).

Some standardization bodies have developed system life management practices that bridge both military and commercial systems (e.g., INCOSE, SOLE, ISO, IEEE, etc.). There are multiple commercial associations involved with defining engineering policies, best practices, and requirements for commercial product and service life management. Each commercial association has a specific focus for the market or domain area where the product is used. Examples of such commercial associations in the U.S. include: American Society of Hospital Engineering (ASHE); Association of Computing Machinery (ACM); American Society of Mechanical Engineers (ASME); American Society for Testing & Materials (ASTM) International; National Association of Home Builders (NAHB); and Internet Society (ISOC), including Internet Engineering Task Force (IETF), and SAE.

In addition, there are several specific resources which provide useful information on product and service life management:

- The *INCOSE Systems Engineering Handbook*, version 3.2.2, identifies several relevant points regarding product and service life management (2011).
- The *Systems Engineering Guidebook for Intelligent Transportation Systems (ITS)*, version 1.1, provides guidance on product changes and system retirement (Caltrans and USDOT 2005).
- *Systems Engineering and Analysis* emphasizes design for supportability and provides a framework for product and service supportability and planning for system retirement (Blanchard and Fabrycky 2006).
- *Modernizing Legacy Systems* identifies strategies for product and service modernization (Seacord, Plakosh, and Lewis 2003).
- "Logistics and Materiel Readiness" (http://www.acq.osd.mil/log/ [1]) provides online policies, procedures, and planning references for product service life extension, modernization, and retirement (OUSD(AT&L) 2011).

- *A Multidisciplinary Framework for Resilience to Disasters and Disruptions* provides insight into architecting a system for extended service life (Jackson 2007).

Good Practices

Major pitfalls associated with systems engineering (SE) after the deployment of products and services can be avoided if the systems engineer:

- Recognizes that the systems engineering process does not stop when the product or service becomes operational.
- Understands that certain life management functions and organizations, especially in the post-delivery phase of the life cycle, are part of the systems engineering process.
- Identifies that modifications need to comply with the system requirements.
- Considers that the users must be able to continue the maintenance activities drawn up during the system requirement phase after an upgrade or modification to the system is made.
- Accounts for changing user requirements over the system life cycle.
- Adapts the support concepts drawn up during development throughout the system life cycle.
- Applies engineering change management to the total system.

Not addressing these areas of concern early in development and throughout the product or service's life cycle can have dire consequences.

Service Life Extension

- Lead Author:
- William Stiffler
- Contributing Author:
- Brian Wells

-

Product and service life extension involves continued use of a product and/or service beyond its original design life. Product and service life extension involves assessing the risks and the life cycle cost (LCC) of continuing the use of the product or service versus the cost of a replacement system.

Service life extension (SLE) emphasizes reliability upgrades and component replacement or rebuilding of the system to delay the system's entry into *wear-out* status due to issues such as expensive sustainment, reliability, safety, and/or performance requirements that can no longer be met. The goal is typically to return the system to as new a condition as possible while remaining consistent with the economic constraints of the program.

SLE is regarded as an environmentally friendly way to relieve rampant waste by prolonging the useful life of retiring products and preventing them from being discarded too early when they still have unused value. However, challenged by fast-changing technology and physical deterioration, a major concern in planning a product SLE is considering to what degree a product or service is fit to have its life extended.

Topic Overview

SLE is typically required in the following circumstances:

- The system no longer meets the system performance or reliability requirements.
- The cost of operation and maintenance exceeds the cost of SLE, or the available budgets.
- Parts are no longer available for repair and maintenance.
- Operation of the system violates rules or regulations, such as environmental or safety regulations.
- Parts of the system are about to reach their operations life limits, which will result in the issue listed above occurring.

It is best if systems engineers use a proactive approach that predicts ahead, so that SLE can be accomplished before the system fails to meet its requirements and before the operations and support costs rise above acceptable limits.

Key factors that must be considered by the systems engineer during service life extension include:

- current life cycle costs of the system
- design life and expected remaining useful life of the system
- software maintenance
- configuration management
- warranty policy
- availability of parts, subsystems, and manufacturing sources
- availability of system documentation to support life extension

System design life is a major consideration for SLE. System design life parameters are established early on during the system design phase and include key assumptions involving safety limits and material life. Safety limits and the properties of material aging are critical to defining system life extension. Jackson emphasizes the importance of architecting for system resiliency in increasing system life. He also points out that a system can be architected to

withstand internal and external disruptions (2007, 91-108). Systems that age through use, such as aircraft, bridges, and nuclear power plants, require periodic inspection to ascertain the degree of aging and fatigue. The results of inspections determine the need for actions to extend the product life (Elliot, Chen, and Swanekamp 1998, sec. 6.5).

Software maintenance is a critical aspect of SLE. The legacy system may include multiple computer resources that have been in operation for a period of many years and have essential functions that must not be disrupted during the upgrade or integration process. Typically, legacy systems include a computer resource or application software program that continues to be used because the cost of replacing or redesigning it is prohibitive. The Software Engineering Institute (SEI) has addressed the need for SLE of software products and services and provides useful guidance in the online library for Software Product Lines (SEI 2010, 1). (See Systems Engineering and Software Engineering for additional discussion of software engineering (SwE) factors to consider.)

Systems engineers have found that service life can be extended through the proper selection of materials. For example, transportation system elements such as highway bridges and rail systems are being designed for extended service life by using special epoxy-coated steel (Brown, Weyers, and Spinkel 2006, 13). Diminishing manufacturing sources and diminishing suppliers need to be addressed early in the SLE process. Livingston (2010) in *Diminishing Manufacturing Sources and Material Shortages (DMSMS) Management Practices* provides a method for addressing product life extension when the sources of supply are an issue. He addresses the product life cycle model and describes a variety of methods that can be applied during system design to minimize the impact of future component obsolescence issues.

During product and service life extension, it is often necessary to revisit and challenge the assumptions behind any previous life cycle cost analysis (and constituent analyses) to evaluate their continued validity and/or applicability early in the process.

Application to Product Systems

Product life extension requires an analysis of the LCC associated with continued use of the existing product versus the cost of a replacement product. In the INCOSE Systems Engineering Handbook, Chapter 3.3 points out that the support stage includes service life extension (2012). Chapter 7 provides a framework to determine if a product's life should be extended (INCOSE 2012). In Systems Engineering and Analysis, Chapter 17 provides an LCC methodology and emphasizes the analysis of different alternatives before deciding on product life extension (Blanchard and Fabrycky 2011).

For military systems, service life extension is considered a subset of modification or modernization. Military systems use well-developed and detailed guidance for SLE programs (SLEP). The Office of the Under Secretary of Defense for Acquisition, Technology, and Logistics (OSD AT&L) provides an online reference for policies, procedures, planning guidance, and whitepapers for military product service life extension (DAU 2011). Continuous military system modernization is a process by which state-of-the-art technologies are inserted continuously into weapon systems to increase reliability, lower sustainment costs, and increase the war fighting capability of a military system to meet evolving customer requirements throughout an indefinite service life.

Aircraft service life can be extended by reducing the dynamic loads which lead to structural fatigue. The Boeing B-52 military aircraft and the Boeing 737 commercial aircraft are prime examples of system life extension. The B-52 was first fielded in 1955 and the Boeing 737 has been fielded since 1967; both aircraft are still in use today.

For nuclear reactors, system safety is the most important precondition for service life extension. System safety must be maintained while extending the service life (Paks 2010). Built-in tests, automated fault reporting and prognostics, analysis of failure modes, and the detection of early signs of wear and aging may be applied to predict the time when maintenance actions will be required to extend the service life of the product. (For additional discussion, see Safety Engineering.)

Application to Service Systems

For systems that provide services to a larger consumer base, SLE involves continued delivery of the service without disrupting consumer use. This involves capital investment and financial planning, as well as a phased deployment of changes. Examples of these concepts can be seen in transportation systems, water treatment facilities, energy generation and delivery systems, and the health care industry. As new technologies are introduced, service delivery can be improved while reducing LCC's. Service systems must continuously assess delivery costs based upon the use of newer technologies.

Water handling systems provide a good example of a service system that undergoes life extension. Water handling systems have been in existence since early civilization. Since water handling systems are in use as long as a site is occupied (e.g., the Roman aqueducts) and upgrades are required as the population expands, such systems are a good example of "systems that live forever." For example, there are still U.S. water systems that use a few wooden pipes since there has been no reason to replace them. Water system life extension must deal with the issue of water quality and the capacity for future users (Mays 2000). Water quality requirements can be further understood from the AWWA Manuals of Water Supply Practices (AWWA 2010).

Application to Enterprises

SLE of a large enterprise, such as the National Astronautics and Space Administration's (NASA) national space transportation system, involves SLE on the elements of the enterprise, such as the space vehicle (shuttle), ground processing systems for launch operations and mission control, and space-based communication systems that support space vehicle tracking and status monitoring. SLE of an enterprise requires a holistic look across the entire enterprise. A balanced approach is required to address the cost of operating older system components versus the cost required to implement service life improvements.

Large enterprise systems, such as oil and natural gas reservoirs which span broad geographical areas, can use advanced technology to increase their service life. The economic extraction of oil and natural gas resources from previously established reservoirs can extend their system life. One such life extension method is to pump special liquids or gases into the reservoir to push the remaining oil or natural gas to the surface for extraction (Office of Natural Gas & Oil Technology 1999).

Other Topics

Commercial product developers have been required to retain information for extended periods of time after the last operational product or unit leaves active service (for up to twenty years). Regulatory requirements should be considered when extending service life (INCOSE 2012).

Practical Considerations

The cost associated with life extension is one of the main inputs in the decision to extend service life of a product or a service. The cost of SLE must be compared to the cost of developing and deploying a new system, as well as the functional utility the user will obtain from each of the alternatives. It is often the case that the funding required for SLE of large complex systems is spread over several fiscal planning cycles and is therefore subject to changes in attitude by the elected officials that appropriate the funding.

The challenges with upgrading a system while it is still being used, which is often the case with SLE, must be understood and planned to avoid serious disruptions to the services the systems provide.

Any SLE must also consider the obsolescence of the systems parts, (e.g., software, amount of system redesign that is required to eliminate the obsolete parts, etc.).

Capability Updates, Upgrades, and Modernization

- Lead Author:
- William Stiffler
- Contributing Author:
- Brian Wells

-

Modernization and upgrades involve changing the product or service to include new functions and interfaces, improve system performance, and/or improve system supportability. The logistic support of a product or service reaches a point in its life where system modernization is required to resolve supportability problems and to reduce operational costs. The *INCOSE Systems Engineering Handbook* (INCOSE 2012) and *Systems Engineering and Analysis* (Blanchard and Fabrycky 2005) both stress the importance of using life cycle costs (LCC) when determining if a product or service should be modernized. Systems can be modernized in the field or returned to a depot or factory for modification.

Design for system modernization and upgrade is an important part of the system engineering process and should be considered as part of the early requirements and design activities. Engineering change proposals (ECPs) are used to initiate updates and modifications to the original system. Product and service upgrades can include new technology insertion, removing old equipment, or adding new equipment. Form, fit, function, and interface (F3I) is an important principle for upgrades where backward compatibility is a requirement.

Topic Overview

Product and service modernization involves the same systems engineering (SE) processes and principles that are employed during the upfront design, development, integration, and testing. The primary differences between product and service modernization are the various constraints imposed by the existing system architecture, design, and components. Modernizing a legacy system requires a detailed understanding of the product or service prior to making any changes. The constraints and the existence of design and test artifacts make it necessary for the systems engineers performing modernization to tailor the traditional development processes to fit the situation.

Product and service modernization occurs for many reasons, including the following:

1. The system or one of its subsystems is experiencing reduced performance, safety, or reliability.

2. A customer or other stakeholder desires a new capability for the system.
3. Some system components may be experiencing obsolescence, including the lack of spare parts.
4. New uses for the system require modification to add capabilities not built into the originally deployed system.

The first three reasons above are discussed in more detail in *Applying Systems Engineering to In-Service Systems: Supplementary Guidance to the INCOSE Systems Engineering Handbook.* (INCOSE UK Chapter 2010).

The UK chapter of the INCOSE developed *Applying Systems Engineering to In-Service Systems: Supplementary Guidance to the INCOSE Systems Engineering Handbook* (INCOSE UK Chapter 2010). This guidance document applies to any system for which multiple systems are produced. These systems may be buildings, transmission networks, aircraft, automobiles or military vehicles, trains, naval vessels, and mass transit systems.

Government and military products provide a comprehensive body of knowledge for system modernization and updates. Key references have been developed by the defense industry and can be particular to their needs.

Key factors and questions that must be considered by the systems engineer when making modifications and upgrades to a product or service include:

- type of system (space, air, ground, maritime, and safety critical)
- missions and scenarios of expected operational usage
- policy and legal requirements that are imposed by certain agencies or business markets
- product or service LCCs
- electromagnetic spectrum usage expected, including change in RF emissions
- system original equipment manufacturer (OEM) and key suppliers, and availability of parts and subsystems
- understanding and documenting the functions, interfaces, and performance requirements, including environmental testing and validation
- system integration challenges posed by the prevalence of system-of-systems solutions and corresponding interoperability issues between legacy, modified, and new systems
- amount of regression testing to be performed on the existing software

Key processes and procedures that should be considered during product and service modernization include:

- legislative policy adherence review and certification
- safety critical review
- engineering change management and configuration control
- analysis of alternatives
- warranty and product return process implementation
- availability of manufacturing and supplier sources and products

Application to Product Systems

Product modernization involves understanding and managing a list of product deficiencies, prioritizing change requests, and handling customer issues associated with product usage. The *INCOSE Systems Engineering Handbook* emphasizes the use of Failure Modes, Effects, and Criticality Analysis (FMECA) to understand the root causes of product failures and provide the basis for making any product changes.

Product modernization uses the engineering change management principle of change control boards to review and implement product changes and improvements. The U.S. Office of the Under Secretary of Defense for Acquisition, Technology, and Logistics (OUSD AT&L) provides an online reference for product modernization and the use of an ECP to document planned product or service modernization efforts.

Product modernization and upgrades require the use of system documentation. A key part of the product change process is to change the supporting system documentation functions, interfaces, modes, performance requirements, and limitations. Both INCOSE (2012) and Blanchard and Fabrycky (2005) stress the importance of understanding the intended usage of the product or service documented in the form of a concept of operations.

If system documentation is not available, reverse engineering is required to capture the proper “as is configuration” of the system and to gain understanding of system behavior prior to making any changes. Seacord, Plakosh, and Lewis's *Modernizing Legacy Systems* (2003) explains the importance of documenting the existing architecture of a system, including documenting the software architecture prior to making any changes. Chapter 5 of Seacord, Plakosh, and Lewis provides a framework for understanding and documenting a legacy system (2003). The authors point out that the product or service software will undergo a transformation during modernization and upgrades. Chapter 5 introduces a horseshoe model that includes functional transformation, code transformation, and architecture transformation (Seacord, Plakosh, and Lewis 2005).

During system verification and validation (after product change), it is important to perform regression testing on the portions of the system that were not modified to confirm that upgrades did not impact the existing functions and behaviors of the system. The degree and amount of regression testing depends on the type of change made to the system and whether the upgrade includes any changes to those functions or interfaces involved with system safety. INCOSE (2012) recommends the use of a requirements verification traceability matrix to assist the systems engineer during regression testing.

It is important to consider changes to the system support environment. Change may require modification or additions to the system test equipment and other support elements such as packaging and transportation.

Some commercial products contain components and subsystems where modernization activities cannot be performed. An example of these types of commercial systems can be seen by looking at consumer electronics, such as radios and computer components. The purchase price of these commercial systems is low enough that upgrades are not economical and are considered cost prohibitive.

Application to Service Systems

Service system modernization may require regulatory changes to allow the use of new technologies and new materials. Service system modernization requires backward compatibility to previous provided service capability during the period of change. Service system modernization also generally spans large geographical areas, requiring a phase-based change and implementation strategy. Transportation systems, such as highways, provide service to many different types of consumers and span large geographical areas. Modernization of transportation systems often requires reverse engineering prior to making changes to understand how traffic monitoring devices such as metering, cameras, and toll tags interface with the rest of the system. The California Department of Transportation's (CDOT's) Systems Engineering Guidebook for Intelligent Transportation Systems (ITS) (2005) adds reverse engineering to the process steps for system upgrade. In addition, this reference points out the need to maintain system integrity and defines integrity to include the accurate documentation of the system's functional, performance, and physical requirements in the form of requirements, design, and support specifications.

Software modernization is discussed in the *Guide to the Software Engineering Body of Knowledge (SWEBOK)* (Bourque and Fairley, 2014).

Application to Enterprises

Enterprise system modernization must consider the location of the modification and the conditions under which the work will be performed. The largest challenge is implementing the changes while the system remains operational. In these cases, disruption of ongoing operations is a serious risk. For some systems, the transition between the old and new configuration is particularly important and must be carefully planned.

Enterprise system modernization may require coordination of changes across international boundaries. Enterprise modifications normally occur at a lower level of the system hierarchy. Change in requirements at the system level would normally constitute a new system or a new model of a system.

The *INCOSE UK Chapter Supplementary Guidance* (2010) discusses the change to the architecture of the system. In cases where a component is added or changed, this change will constitute a change to the architecture. As an example, the global positioning system (GPS) is an enterprise system implemented by the United States military but used by both commercial and government consumers worldwide. Modernization may involve changes to only a certain segment of the enterprise, such as the ground user segment to reduce size, weight, and power. Modernization may only occur in certain geographical areas of operation. For example, the air transportation system consists of multiple countries and governing bodies dispersed over the entire world. Changes can occur locally or can require coordination and integration world-wide.

Other Topics

The Vee Model for Modifications

Figure 1 below illustrates how the standard Vee model would be applied to a system modification. This Vee model is for the entire system; the key point is that if a modification is being initiated at a lower level of the system hierarchy, the Vee model must be entered at that level as shown in the figure. The figure shows three entry points to the Vee model. As the *INCOSE UK Chapter Supplementary Guidance* (2010) points out, the Vee model may be entered multiple times during the life of the system.

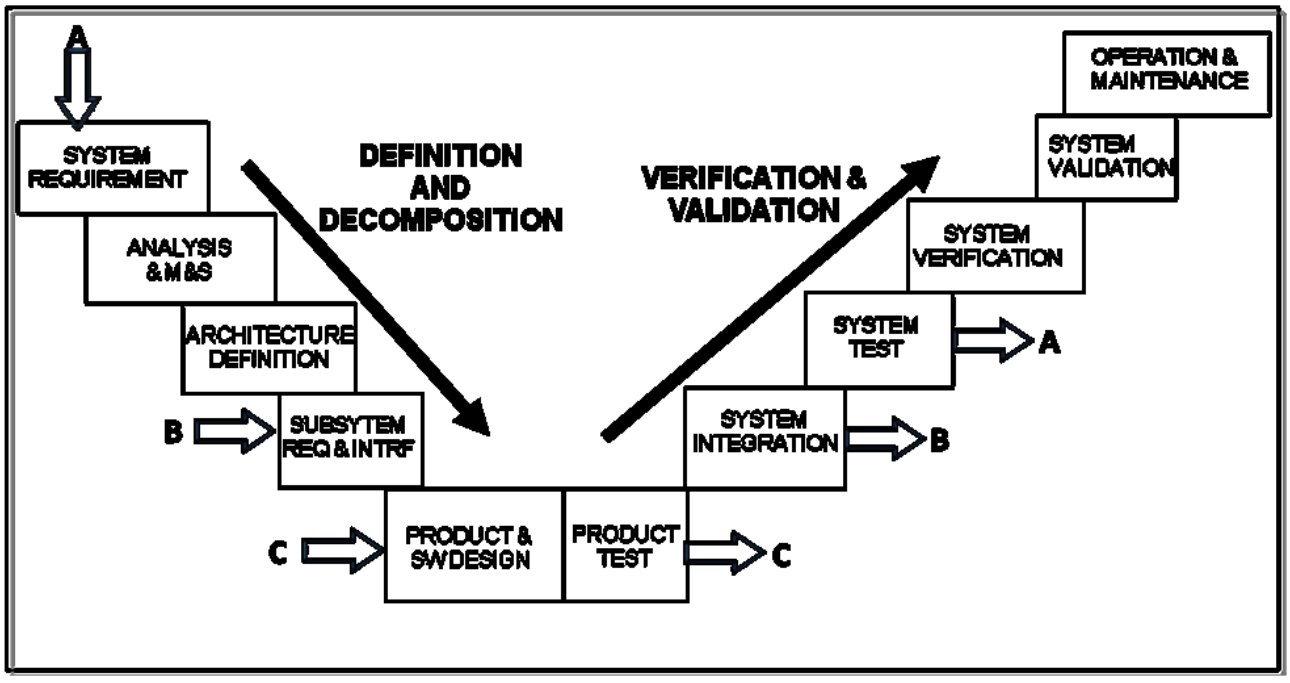

Figure 1. The Vee Model for Modifications at the Three Different Levels. (SEBoK Original)

A change to the system that does not change the system capabilities but does change the requirements and design of a subsystem that may be introduced into the process at point B on the Vee model (see Figure 1). Changes of this type

could provide a new subsystem, such as a computer system, that meets the system-level requirements but has differences from the original, which necessitates modifications to the lower-level requirements and design, such as changing disk memory to solid state memory. The process for implementing changes starting at this point has been described by Nguyen (2006). Modification introduced at points B or C (in Figure 1) necessitate flowing the requirements upward through their "parent" requirements to the system-level requirements.

There are many cases where the change to a system needs to be introduced at the lowest levels of the architectural hierarchy; here, the entry point to the process is at point C on the Vee model. These cases are typically related to obsolete parts caused by changes in technology or due to reliability issues with subsystems and parts chosen for the original design. A change at this level should be F3I compatible so that none of the higher-level requirements are affected. The systems engineer must ensure there is no impact at the higher levels; when this does occur, it must be immediately identified and worked out with the customer and the other stakeholders.

In "Life extension of Civil Infrastructural works - a systems engineering approach" van der Laan (2008) provides a maintenance process that interacts with the system engineering process, represented by the Vee model. His life extension (or modernization) process model includes reverse engineering to obtain the system definition necessary for the modernization process. Consideration of the total lifecycle of the system will result in the capture of all of the records necessary for later upgrade; however, for many reasons, the systems engineer will find that the necessary information has not been captured or maintained.

Practical Considerations

As pointed out by the *INCOSE UK Chapter Supplementary Guidance* (2010) there may be multiple modifications to a system in its lifetime. Often these modifications occur concurrently. This situation requires special attention and there are two methods for managing it. The first is called the "block" method. This means that a group of systems are in the process of being modified simultaneously and will be deployed together as a group at a specific time. This method is meant to ensure that at the end state, all the modifications have been coordinated and integrated so there are no conflicts and no non-compliance issues with the system-level requirements. The second method is called continuous integration and is meant to occur concurrently with the block method. Information management systems provide an example of a commercial system where multiple changes can occur concurrently. The information management system hardware and network modernization will cause the system software to undergo changes. Software release management is used to coordinate the proper timing for the distribution of system software changes to end-users (Michigan Department of Information Technology, 2008).

Application of Commercial-Off-the-Shelf Components

Currently, a prominent consideration is the use of commercial-off-the-shelf (COTS) components. The application of COTS subsystems, components, and technologies to system life management provides a combination of advantages and risks. The first advantage is the inherent technological advancements that come with COTS components. COTS components continue to evolve toward a higher degree of functional integration. They provide increased functionality, while shrinking in physical size. The other advantage to using COTS components is that they typically have a lower cost.

The risks associated with using COTS during system life management involve component obsolescence and changes to system interfaces. Commercial market forces drive some components to obsolescence within two years or less. Application of COTS requires careful consideration to form factor and interface (physical and electrical).

System Disposal and Retirement

- Lead Author:
- Brian Wells

-

Product or service disposal and retirement is an important part of system life management. At some point, any deployed system will become one of the following: uneconomical to maintain; obsolete; or unrepairable. A comprehensive systems engineering process includes an anticipated equipment phase-out period and takes disposal into account in the design and life cycle cost assessment. (See other knowledge areas in Part 3 for discussion on life cycle metrics and assessment.)

A public focus on sustaining a clean environment encourages contemporary systems engineering (SE) design to consider recycling, reuse, and responsible disposal techniques. (See Systems Engineering and Environmental Engineering for additional discussion.)

Topic Overview

According to the INCOSE Systems Engineering Handbook (2012), "The purpose of the disposal process is to remove a system element from the operation environment with the intent of permanently terminating its use; and to deal with any hazardous or toxic materials or waste products in accordance with the applicable guidance, policy, regulation, and statutes." In addition to technological and economical factors, the system-of-interest (SoI) must be compatible, acceptable, and ultimately address the design of a system for the environment in terms of ecological, political, and social considerations.

Ecological considerations associated with system disposal or retirement are of prime importance. The most concerning problems associated with waste management include:

- Air Pollution and Control,
- Water Pollution and Control,
- Noise Pollution and Control,
- Radiation, and
- Solid Waste.

In the US, the Environmental Protection Agency (EPA) and the Occupational Safety and Health Administration (OSHA) govern disposal and retirement of commercial systems. Similar organizations perform this function in other countries. OSHA addresses hazardous materials under the 1910-119A List of Highly Hazardous Chemicals, Toxics, and Reactives (OSHA 2010). System disposal and retirement spans both commercial and government developed products and services. While both the commercial and government sectors have common goals, methods differ during the disposition of materials associated with military systems.

US DoD Directive 4160.21-M, *Defense Material Disposition Manual* (1997) outlines the requirements of the Federal Property Management Regulation (FPMR) and other laws and regulations as appropriate regarding the disposition of excess, surplus, and foreign excess personal property (FEPP). Military system disposal activities must be compliant with EPA and OSHA requirements.

Application to Product Systems

Product system retirement may include system disposal activities or preservation activities (e.g., mothballing) if there is a chance the system may be called upon for use at a later time.

Systems Engineering and Analysis has several chapters that discuss the topics of design for goals such as "green engineering," reliability, maintainability, logistics, supportability, producibility, disposability, and sustainability. Chapter 16 provides a succinct discussion of green engineering considerations and ecology-based manufacturing. Chapter 17 discusses life cycle costing and the inclusion of system disposal and retirement costs (Blanchard and Fabrycky 2011).

Some disposal of a system's components occurs during the system's operational life. This happens when the components fail and are replaced. As a result, the tasks and resources needed to remove them from the system need to be planned well before a demand for disposal exists.

Transportation of failed items, handling equipment, special training requirements for personnel, facilities, technical procedures, technical documentation updates, hazardous material (HAZMAT) remediation, all associated costs, and reclamation or salvage value for precious metals and recyclable components are important considerations during system planning. Phase-out and disposal planning addresses when disposal should take place, the economic feasibility of the disposal methods used, and what the effects on the inventory and support infrastructure, safety, environmental requirements, and impact to the environment will be (Blanchard 2010).

Disposal is the least efficient and least desirable alternative for the processing of waste material (Finlayson and Herdlick 2008).

The EPA collects information regarding the generation, management and final disposition of hazardous wastes regulated under the Resource Conservation and Recovery Act of 1976 (RCRA). EPA waste management regulations are codified at 40 C.F.R., parts 239-282. Regulations regarding management of hazardous wastes begin at 40 C.F.R. part 260. Most states have enacted laws and promulgated regulations that are at least as stringent as federal regulations.

Due to the extensive tracking of the life of hazardous waste, the overall process has become known as the "cradle-to-grave system". Stringent bookkeeping and reporting requirements have been levied on generators, transporters, and operators of treatment, storage, and disposal facilities that handle hazardous waste.

Unfortunately, disposability has a lower priority compared to other activities associated with product development. This is due to the fact that typically, the disposal process is viewed as an external activity to the entity that is in custody of the system at the time. Reasons behind this view include:

- There is no direct revenue associated with the disposal process and the majority of the cost associated with the disposal process is initially hidden.
- Typically, someone outside of SE performs the disposal activities. For example, neither a car manufacturer nor the car's first buyer may be concerned about a car's disposal since the car will usually be sold before disposal.

The European Union's Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH) regulation requires manufacturers and importers of chemicals and products to register and disclose substances in products when specific thresholds and criteria are met (European Parliament 2007). The European Chemicals Agency (ECHA) manages REACH processes. Numerous substances will be added to the list of substances already restricted under European legislation; a new regulation emerged when the Restriction on Hazardous Substances (RoHS) in electrical and electronic equipment was adopted in 2003.

Requirements for substance use and availability are changing across the globe. Identifying the use of materials in the supply chain that may face restriction is an important part of system life management. System disposal and retirement requires upfront planning and the development of a disposal plan to manage the activities. An important consideration during system retirement is the proper planning required to update the facilities needed to support the system during retirement, as explained in the *California Department of Transportation Systems Engineering*

Guidebook (2005).

Disposal needs to account for environmental and personal risks associated with the decommissioning of a system and all hazardous materials involved. The decommissioning of a nuclear power plant is a prime example of hazardous material control and exemplifies the need for properly handling and transporting residual materials resulting from the retirement of certain systems.

The US Defense Logistics Agency (DLA) is the lead military agency responsible for providing guidance for worldwide reuse, recycling, and disposal of military products. A critical responsibility of the military services and defense agencies is demilitarization prior to disposal.

Application to Service Systems

An important consideration during service system retirement or disposal is the proper continuation of services for the consumers of the system. As an existing service system is decommissioned, a plan should be adopted to bring new systems online that operate in parallel with the existing system so that service interruption is kept to a minimum. This parallel operation needs to be carefully scheduled and can occur over a significant period of time.

Examples of parallel operation include phasing in new Air Traffic Control (ATC) systems (FAA 2006), the migration from analog television to new digital television modulation (FCC 2009), the transition to Internet protocol version 6 (IPv6), maintaining water handling systems, and maintaining large commercial transportation systems, such as rail and shipping vessels.

The *Systems Engineering Guidebook for Intelligent Transportation Systems (ITS)* provides planning guidance for the retirement and replacement of large transportation systems. Chapter 4.7 identifies several factors which can shorten the useful life of a transportation system and lead to early retirement, such as the lack of proper documentation, the lack of effective configuration management processes, and the lack of an adequate operations and maintenance budget (Caltrans, and USDOT 2005).

Application to Enterprises

The disposal and retirement of large enterprise systems requires a phased approach, with capital planning being implemented in stages. As in the case of service systems, an enterprise system's disposal and retirement require parallel operation of the replacement system along with the existing (older) system to prevent loss of functionality for the user.

Other Topics

See the OSHA standard (1996) and EPA (2010) website for references that provide listings of hazardous materials. See the DLA Disposal Services website [1] for disposal services sites and additional information on hazardous materials.

Practical Considerations

A prime objective of systems engineering is to design a product or service such that its components can be recycled after the system has been retired. The recycling process should not cause any detrimental effects to the environment.

One of the latest movements in the industry is green engineering. According to the EPA, green engineering is the design, commercialization, and use of processes and products that are technically and economically feasible while minimizing:

- the generation of pollutants at the source; and
- the risks to human health and the environment.

See Environmental Engineering for additional information.

Part 3d: Relevant Standards

Knowledge Area: Systems Engineering Standards

Systems Engineering Standards

Contents of this Knowledge Area

- Why Standards? (Garry Roedler) (Bill Bearden, David Endler, and Mike Yokell)
- Systems Engineering Related Standards Landscape (Garry Roedler) (Bill Bearden, David Endler, and Mike Yokell)
- Alignment and Comparison of Systems Engineering Standards (Garry Roedler) (William Bearden, David Endler, and Mike Yokell)
- Application of Systems Engineering Standards (Garry Roedler) (William Bearden, David Endler, and Mike Yokell)

- Lead Author:
- Garry Roedler
- Contributing Authors:
- Bill Bearden, David Endler, and Mike Yokell

-

This knowledge area (KA) focuses on the standards and key references (hereafter referred to as standards) that are relevant to systems engineering. This KA examines the importance of standards, the types of standards, some of the key standards, the alignment efforts to achieve a consistent set of standards, and the suitable application of these standards. Note that many of these standards have been used as references throughout Part 3.

Topics

Each part of the SEBoK is divided into KA's, which are groupings of information with a related theme. The KA's, in turn, are divided into topics. This KA contains the following topics:

- Why Standards?
- Systems Engineering Related Standards Landscape
- Alignment and Comparison of the Standards
- Application of Systems Engineering Standards

See the article Matrix of Implementation Examples for a mapping of case studies and vignettes included in Part 7 to topics covered in Part 3.

References

None.

Why Standards?

- Lead Author:
- Garry Roedler
- Contributing Authors:
- Bill Bearden, David Endler, and Mike Yokell

-

There are many standards and guides across the industry that are related to Systems Engineering. A common question that comes up when considering the use of standards and guides is "Why Standardize?." This section will take a look at this question. This knowledge area, and particularly this article, will view standards as including formal documents that are developed by a Standards Development Organization (such as ISO or IEEE), deFacto standards that are generally accepted works, bodies of knowledge, and key guides that provide a consensus view. A list of the types of standards is provided in Systems Engineering Related Standards Landscape, Standards Taxonomies and Types of Standards, Table 1.

Why Standardize? The need and challenges for standards in SE

Standardization in engineering can help ensure quality, consistency, safety, efficiency, and effectiveness for products and projects throughout the life cycles, leading to improved communication, reduced errors, and faster cycle times. However, although there are many benefits from standardization, there are also some limitations or hinderances that can come from standardization. Table 1 provides a look at the Pros and Cons of standardization. For most projects and organizations, the Pros tend to outweigh the Cons. The use of the term standardization in this KA includes the definition, adaptation, tailoring, usage, assessment and improvement of standards.

Table 1. Pros and Cons of SE Standardization (G. Roedler, Used with Permission)

Focus	Pros	Cons
Timing & Effectivness	Can help incorporate broad lessons learned and proven practices. Can help ensure technologies are not only effective, but also secure and safe for users.	Potential immaturity of a topic for standardization; i.e., standard can be developed too early. It can take a long time to create an effective standard; it may continue to trail the focus methods, technology, etc.
Innovation	Can provide a baseline for tool development, methods and applications allowing engineers to focus on innovation for new solutions, rather than reinventing the wheel for performing basic tasks on projects. As innovation occurs, the standardization generally helps to spread the knowledge.	Can somewhat stifle innovation when new approaches are needed due to novel situations.
Quality and Consistency	Standardized processes and system elements can help ensure that products and systems are built consistently, reducing variations and improving overall quality. Process standards aim to help ensure consistency in the performance of processes and their outputs, regardless of the location or personnel involved.	In some cases, standardized processes can challenge responsiveness or agility.
Communication & Collaboration	Can help converge practices, which aids communication, teaming/collaboration, knowledge management. Standardized processes, practices, formats, symbols, and conventions can facilitate clear and efficient communication among engineers and other stakeholders.	Can drive communication paths or workflows that are not optimal, if not properly tailored for the project or organizational situation.

Efficiency & Productivity	Standardized designs and processes can promote faster product development cycles, as engineers can reuse existing, pre-approved elements and methods. Streamlined processes generally improve efficiency by reducing waste: time and resources. Time and resources then can be focused on the solution or business requirements rather than on how to perform the engineering.	In cases with high levels of uncertainty and/or change, agility in the engineering processes and design can be needed. This can be more difficult if appropriate tailoring of the standards is not proactively considered. Also, all projects are not the same. So, if tailoring for the project specific characteristics is not done, it can lead to inefficiencies.
Knowledge Management	Standards can help to document lessons learned for processes and products. For engineering, standards can help provide the memory that could otherwise be lost. When people leave an organization or project, they take their knowledge with them. So, these entities need to capture the "memory". Documenting knowledge assets using standards or standard references can improve searches for specific information.	When there is a high likelihood of change (technology, processes, environments, etc.), especially in short intervals, standards as a means of capturing the "memory" can lead to obsolescence of the knowledge assets shortly after the documentation.
Costs	Standardization can lead to lower material costs for product lines and designs with more stability. Standardization can also help reduce the cost of training, tools, and knowledge transfer.	When there is a high likelihood of change, standardization will not necessarily reduce the cost of materials, training, etc. If the change has not been accounted for due to the standardization, there can be an additional level of resistance to overcome. Adaptability becomes more important.
Scalability	Easier to scale engineering processes and services, as common practices and tools can be reused across multiple projects	
Interoperability	Standardization can help ensure that different systems and elements can work together, promoting interoperability and reducing integration challenges.	

Considerations for standardization

Implementing standards with a full life cycle approach:

When an organization or project implements a standard, it should be a full life cycle approach with respect to the standard in order to gain the greatest benefit. This includes the evaluation of alternative standards, selection, adaptation or tailoring, assessment of results, and improvement actions. ISO/IEC/IEEE 24748-1 and ISO/IEC/IEEE 24748-2 provide guidance on life cycle management, process tailoring, and other life cycle process topics that can help in the implementation of standards.

Assessing the readiness of a technical topic for the definition or usage of standards:

For the definition of a new topic for standardization, it is good to perform a study of the readiness for standards based on the maturity of the concepts, convergence of the principles and theory, and acceptance of proven practices. The study includes an assessment of the industry consensus on the topic. It is also useful to assess the relevance and maturity of a standard with respect to the project application of the topic of the standard. For example, if the project is using a technology covered by a standard, but the project's implementation of the technology is beyond that of the standard, then it could be an impediment to try to use the standard.

Agility and standardization:

These two things are not necessarily counter to each other. Engineering organizations or projects can tailor and adapt the standards, such as ISO/IEC/IEC 15288, to help define their processes and approaches considering agility necessary for situations with more uncertainty and likelihood for change. A paper from the NDIA SED and INCOSE titled "ISO/IEC/IEEE 15288 Meets Lean Agile." details the use of 15288 in an agile approach in the defense environment. However, much of the content applies to projects and systems in any environment. It

describes the use of 15288 in a lean agile approach focusing on lean agile principles, such as customer centricity, systems thinking, multiple horizons of planning, assuming variability and preserving options, iterative development with incremental deliveries and rapid feedback loops, data-driven decisions, decentralized decisions, and more. ISO/IEC/IEEE 24748-1 and ISO/IEC/IEEE 24748-2 provide guidance on life cycle management, process tailoring, and other life cycle process topics that can help in adapting standards for project specific needs, such as agility.

The balance between standardization and project specific needs:

As pointed out in the preceding subsections and Table 1, for the standardization to be most effective, there is usually a need to determine the project specific needs and tailor the standardized elements (process, design, tools, methods, etc.) to best meet the needs of the project. There is no one-size fits all for all projects, and typically, copy and paste or boilerplates don't work as the context and many variables are different. However, it is also important to avoid the "not invented here" mindset for the use standards. Finally, it is important, yet even more challenging, to find the right balance when many organizations are involved in the project.

Perspectives from key stakeholders

The following are a couple quotes regarding the importance and use of standards from ISO and IEEE, two key engineering standards development organizations (SDOs).

Per ISO:

> Standards ensure consistency of essential features of goods and services, such as quality, ecology, safety, economy, reliability, compatibility, interoperability, efficiency and effectiveness.
>
> Standards codify ... technology and facilitate its transfer. Standards are therefore an invaluable source of knowledge.
>
> (https:/ / www. iso. org/ sites/ ConsumersStandards/ 1_standards. html#:~:text=How%20do%20standards%20help?,are%20aligned%20in%20this%20way. 20250331)

Per IEEE:

> Standards help fuel compatibility and interoperability and simplifies product development, and speeds time-to-market. Standards also make it easier to understand and compare competing products. As standards are globally adopted and applied in many markets, they also fuel international trade.
>
> (https:/ / standards. ieee. org/ beyond-standards/ what-are-standards-why-are-they-important/ #:~:text=This%20helps%20fuel%20compatibility%20and,they%20also%20fuel%20international%20trade. 20250331)

And finally, a quote the sums up the importance from a government project and contractor perspective:

> "Technical standards provide the corporate process memory needed for a disciplined systems engineering approach and help ensure that the government and its contractors understand the critical processes and practices necessary to take a system from design to production, and through sustainment." (Welby, S. 2013)

Evolution of SE standards

Systems engineering related standards have evolved over the past few decades as the SE discipline has matured and evolved. These references have continued to incorporate the lessons learned and changes in approaches and methods to ensure they reflect current, proven practices. Along this evolution path, there has been collaboration to help align the references across the industry associations and standards development organizations (more is discussed on this in Alignment and Comparison of Systems Engineering Standards. Figure 1 provides a graphical view of the evolution of a subset of the key SE related standards.

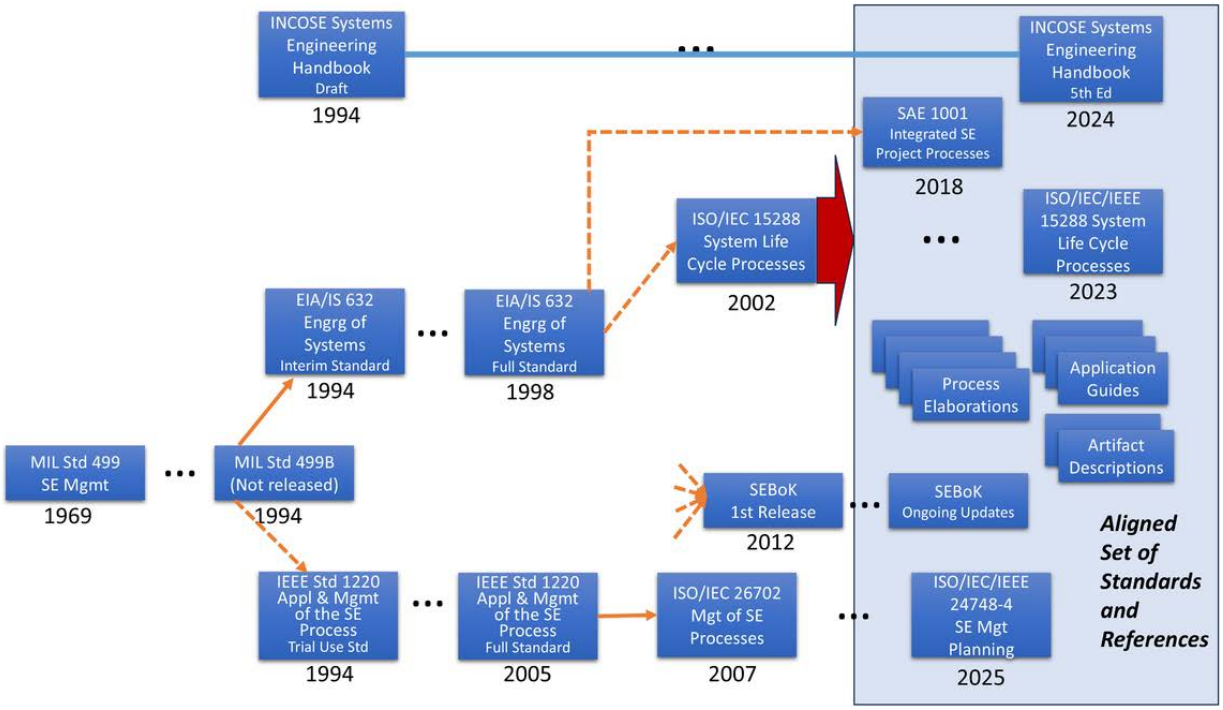

Figure 1. Evolution of Key SE Standards and References (Roedler, adapted from Roedler 2023). Reprinted with permission of Garry Roedler. All other rights are reserved by the copyright owner.

Until the early 1990's, MIL-STD-499 (initially released in 1969) and subsequent revisions were the first and only SE standards developed. In 1994, it transitioned to an industry standard, EIA/IS 632. Around the same time, INCOSE started development of its Systems Engineering Handbook (SEH). Figure 1 shows the ongoing evolution of these documents, as well as the publication of ISO/IEC 15288, which later also became a joint standard with the IEEE. With the dramatic uptake of 15288, the latest revision of ANSI/EIA 632 was fully aligned with 15288 with a scope change and published as SAE 1001. Finally, the SEBoK, started its development in 2009 and was first published in 2012, as a broader reference that serves as a guide to the SE Body of Knowledge.

Systems Engineering Related Standards Landscape

- Lead Author:
- Garry Roedler
- Contributing Authors:
- Bill Bearden, David Endler, and Mike Yokell

-

There are a multitude of standards across a number of standards development organizations (SDOs) that are related to systems engineering and systems domains. This topic examines the types of standards and provides a summary of the relevant standards for systems engineering (SE).

Standards Taxonomies and Types of Standards

There are many types of standards that focus on different aspects of SE. Table 1 provides the types of the current standards and a description of each type.

Table 1. Types of Systems Engineering Standards. (SEBoK Original)

Standard Type	Description of Type
Concepts and Terminology	• Defines the terminology and describes the concepts of a specific domain.
Process	• Defines a specific process or set of processes, giving normative requirements for the essential elements of the process or processes. • It can give guidance to the requirements.
Requirements	• Defines the requirements for something. • Most often used for actions, activities, or practices and not objects (see specifications).
Procedure (Practice, Activity)	• Defines instructions, approach, or requirements on how to do something. • Sometimes a description of best practices.
Application Guides / Guidance	• Defines guidelines or provides interpretation of a published standard.
Management System	• Defines requirements for management of a specific focus area.
Specification	• Defines, describes, or identifies something precisely, including its requirements. • Usually defines requirements, design, and functionality of a product, system, or project and is normative.
Artifact Description	• Defines the form, attributes, content requirements, or properties of an artifact.
Reference Model	• Defines an abstract or conceptual framework that provides a structured means to understand and communicate a system, architecture or element. • Often used as a mechanism to gain commonality and interoperability.
Process Reference Model (PRM)	• Defines a collection of processes necessary and sufficient to achieve a nominated business outcome.
Process Assessment Model (PAM)	• Defines requirements and guidance for assessing attributes of nominated processes or attributes of a nominated collection of processes.

Guide to Body of Knowledge (BOK)	• Defines a collection and description of the current knowledge sources in a domain, or a guide to knowledge sources that comprise the body of knowledge.

Additionally, a taxonomy of the SE related standards can help to understand the available set of standards. A standards taxonomy is defined as an orderly classification of standards according to their attributes and relationships. Figure 1 provides an example of a taxonomy for the SE related standards.

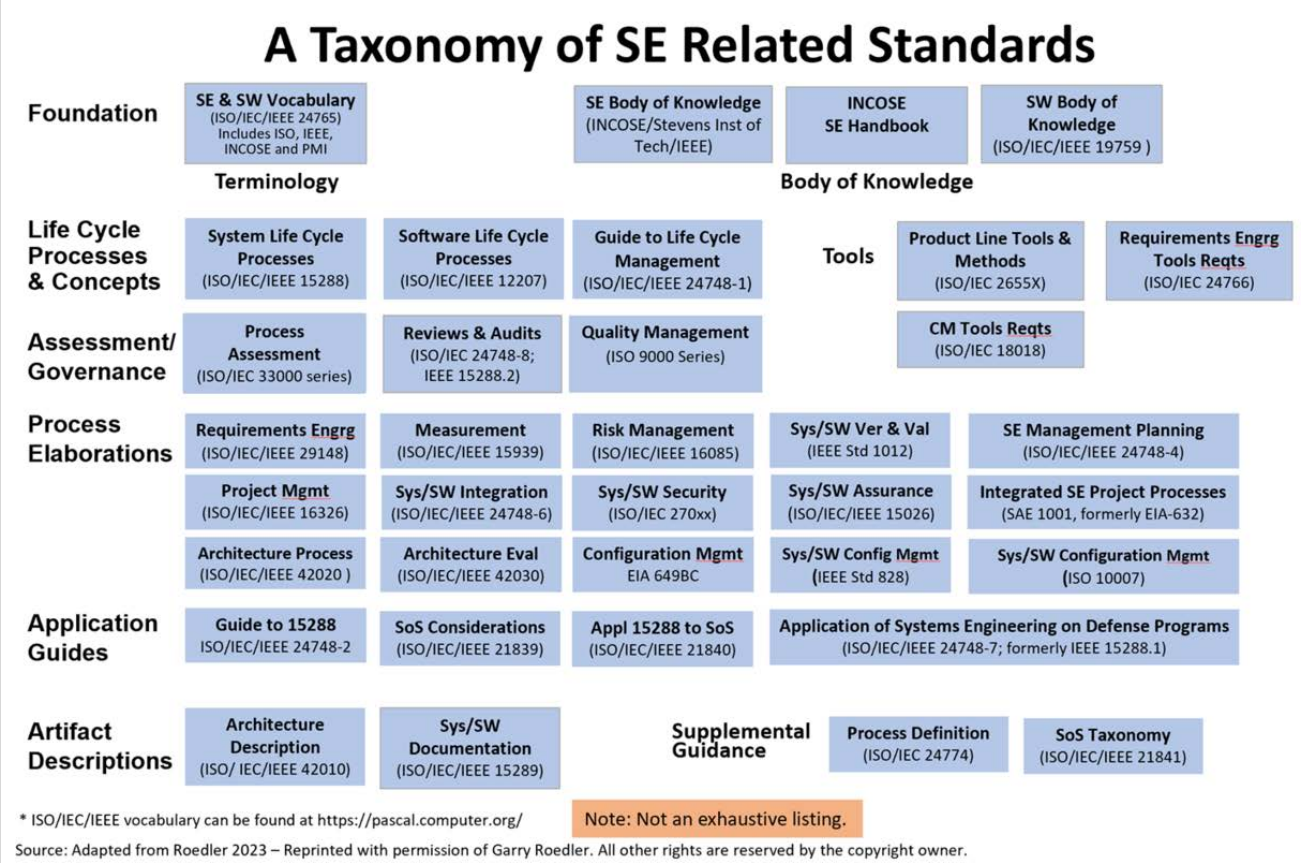

Figure 1. A Taxonomy of SE Related Standards (Adapted from Roedler 2023). Reprinted with permission of Garry Roedler. All other rights are reserved by the copyright owner.

Description of the SE Standards Categories Presented in the Sample Taxonomy

Figure 1 illustrates the focus and level of detail for many of the SE related standards. This figure shows that there are different purposes or objectives for these knowledge assets. The following provides a brief description of the objective for each category in the sample taxonomy. Each of the categories provides specific utility to the SE stakeholders.

Foundation – Vocabulary: This provides a common set of terminology and definitions from across a wide range of standards and references for systems engineering. It includes the vocabulary from ISO/IEC JTC1/SC7, IEEE, INCOSE, and PMI. The vocabulary is both published in ISO/IEC/IEEE 24765, Vocabulary and in an online resource called SEVOCAB at https://pascal.computer.org/.

Foundation – Body of Knowledge: This includes resources that are either published as bodies of knowledge for systems engineering or related areas or are recognized consensus references that cover the breadth of systems engineering. The SEBoK is the sole body of knowledge for SE. The INCOSE SE Handbook covers the breadth of SE and is the key resource used for SE Certification.

Life Cycle Processes and Concepts: This includes the top-level standards and references that identify and define the system life cycle processes and the concepts that are essential for understanding, planning, and executing system life cycles and processes.

Assessment / Governance: This includes standards that are focused on the assessment or governance of processes, products, or other concerns in the engineering of systems or their life cycles.

Process Elaborations: This includes standards that focus specifically on one or more processes. These standards provide lower level details about the definitions, application, and other considerations that aid the planning and execution of the processes. The processes trace to the system life cycle processes identified in ISO/IEC/IEEE 15288, the INCOSE SE Handbook, and/or the SEBoK.

Application Guides: This includes the standards and references that provide key insights and guidance for the other standards and help users to understand the potential considerations for planning and executing the standards. Some of these standards and guides provide useful elaborations or notes regarding specific information or requirements in the standards or topics they refer to, such as ISO/IEC/IEEE 24748-2, A guide for the application of ISO/IEC/IEEE 15288.

Artifact Descriptions: This includes descriptions and/or requirements for specific artifacts (or information items) related to the system life cycle processes.

Tools: This includes standards that provide information or requirements related to tools that are applicable to the system life cycle processes.

Other Guidance: This includes any guidance that is outside of the scope of the other categories in the taxonomy.

Systems Engineering Related Standards

Summary of Systems Engineering Related Standards

Table 2 contains a partial list of SE related standards. This table does not include all SE related standards, as there are many are focused on a specific domain, sector, or user group (e.g., it does not include standards from a specific government agenda). The table does include standards that are considered to be widely applicable to systems engineering and systems life cycle management system life cycle processes, such as ISO/IEC/IEEE 15288 (2023). A link to the official abstract or information page has been provided in the first column for each standard.

Table 2. Summary of Systems Engineering Standards and Guides. (SEBoK Original)

Standard or Guide	Title
ISO/IEC/IEEE 15288 [1]	System life cycle processes
SEBoK	Guide to the Systems Engineering Body of Knowledge (SEBoK)
INCOSE SE Handbook 5th Ed [1]	INCOSE Systems Engineering Handbook (5th Edition)
SAE 1001 [1]	Integrated Project Processes for Engineering a System (replaced ANSI/EIA 632)
NATO AAP-48 [4]	NATO System Life Cycle Processes
SE Vision 2035 (INCOSE) [2]	Systems Engineering Vision 2035: Engineering Solutions for a Better World
ISO/IEC/IEEE 15026-1 [3]	Systems and software assurance concepts and vocabulary
ISO/IEC/IEEE 15026-2 [4]	Assurance case
ISO/IEC/IEEE 15026-3 [5]	System integrity levels

ISO/IEC/IEEE 15026-4 [6]	Assurance in the life cycle
ISO/IEC/IEEE 15289 [5]	Content of life-cycle information items (documentation)
ISO/IEC/IEEE 15939 [7]	Measurement process
ISO/IEC/IEEE 16085 [8]	Risk management
ISO/IEC/IEEE 16326 [4]	Project management
ISO/IEC/IEEE 21839 [9]	System of systems (SoS) considerations in life cycle stages of a system
ISO/IEC/IEEE 21840 [10]	Guidelines for the utilization of ISO/IEC/IEEE 15288 in the context of system of systems (SoS)
ISO/IEC/IEEE 21841 [11]	Taxonomy of system of systems (SoS)
ISO/IEC/IEEE 24641 [11]	Methods and tools for model-based systems and software engineering
ISO/IEC/IEEE 24748-1 [2]	Guidelines for life cycle management
ISO/IEC/IEEE 24748-2 [12]	Guidelines for the application of ISO/IEC/IEEE 15288
ISO/IEC/IEEE 24748-4 [13]	Systems engineering management planning
ISO/IEC/IEEE 24748-6 [14]	System and software integration
ISO/IEC/IEEE 24748-7 [15]	Application of systems engineering on defense programs (previously IEEE 15288.1)
ISO/IEC/IEEE 24748-8 [16]	Technical reviews and audits on defense programs (previously IEEE 15288.2)
ISO/IEC/IEEE 24748-9 [17]	Application of system and software life cycle processes in epidemic prevention and control systems
ISO/IEC/IEEE 24748-10 [18]	Guidelines for systems engineering agility
ISO/IEC/IEEE 24765 [19]	Systems and software engineering - Vocabulary
ISO/IEC/IEEE 26550 [20]	Reference model for product line engineering and management
ISO/IEC/IEEE 26580 [21]	Methods and tools for the feature-based approach to software and systems product line engineering
ISO/IEC/IEEE 29148 [22]	Requirements engineering
ISO/IEC/IEEE 42010 [23]	Architecture description
ISO/IEC/IEEE 42020 [24]	Architecture processes
ISO/IEC/IEEE 42024 [25]	Architecture fundamentals
ISO/IEC/IEEE 42030 [26]	Architecture evaluation framework
ISO/IEC/IEEE 42042 [27]	Reference architectures
ISO/IEC 29110 [28]	Standards and guides for very small entities (VSEs) (Multi-part set)
ISO/IEC TS 33060 [29]	Process assessment model for system life cycle processes
ISO 19450 [30]	Object Process Methodology (OPM)
ISO 9001 [31]	Quality Management Systems - Requirements
ISO 10007 [32]	Guidelines for configuration management

Practical Considerations

Key pitfalls and good practices related to systems engineering standards are described in the next two sections.

Pitfalls

Some of the key pitfalls encountered in the selection and use of SE standards are provided in Table 3.

Table 3. Pitfalls in Using Systems Engineering Standards. (SEBoK Original)

Pitfall Name	Pitfall Description
Turnkey Process Provision	• Expecting the standard to fully provide your SE processes without any elaboration or tailoring.
No Need for Product Knowledge	• Expecting that the standard can be used without any functional or domain knowledge since the standard is the collective industry knowledge.
No Process Integration	• Lack of integrating the standards requirements with the organization or project processes.

Good Practices

Some good practices as gathered from the references are provided in Table 4.

Table 4. Good Practices in Using Systems Engineering Standards. (SEBoK Original)

Good Practice Name	Good Practice Description
Tailor for Business Needs	• Tailor the standard within conformance requirements to best meet business needs.
Integration into Project	• Requirements of the standard should be integrated into the project via processes or product/service requirements.

Alignment and Comparison of Systems Engineering Standards

- Lead Author:
- Garry Roedler
- Contributing Authors:
- William Bearden, David Endler, and Mike Yokell

-

Over the past two decades, standards development organizations (SDOs) and other industry associations have been working collaboratively to align the systems engineering (SE) and software engineering (SwE) standards. The objective is to have a set of standards that can easily be used concurrently within both engineering disciplines, and eventually throughout all engineering disciplines, with common terminology and concepts.

Problem Statement

Previously, SE and SwE standards used different terminology, process sets, process structures, levels of prescription, and audiences. These differences have been both between systems and software, and to some extent, within each. The problem has been exacerbated, in whole or part, by competing standards (Roedler 2010). Additionally, new challenges emerged, such as agile, model-based, and digital approaches, as well as new technologies as the discipline continued to evolve.

If alignment efforts do not have the commitment from all of the stakeholders, especially the SDOs, it can further drive proliferation of standards, as is indicated in Figure 1.

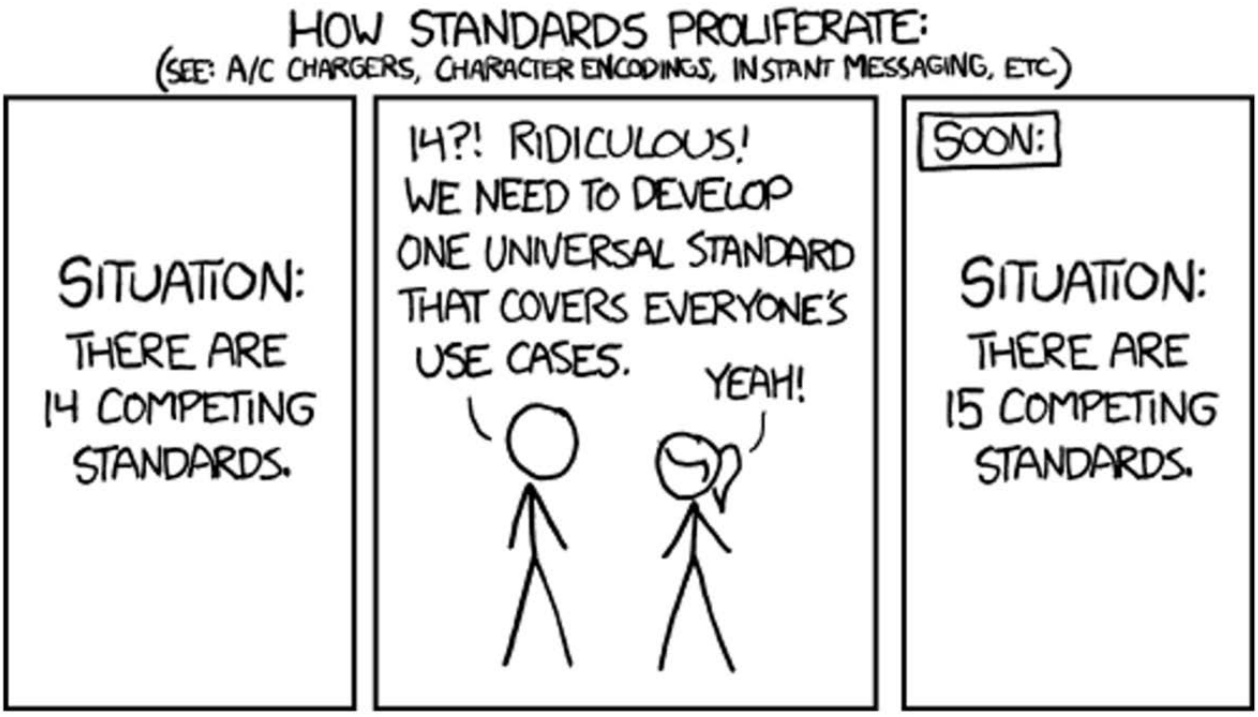

Figure 1. Proliferation of Standards. Used with permission. https://xkcd.com/927

Root Cause

The root causes of this problem include (Roedler 2010):

- Culture – Concepts such as "we're different," "not invented here," etc. Culture change is complicated by the vast number of changes influencing engineering teams and environments today.
- Organizational – Structures with different SDOs, teams, committees, etc. This is further challenged by changes in team structures as agile approaches became more common. And different teams within a single organization can be implementing very different norms as the organization transitions.
- Competition – Many SDOs exist. Each SDO is motivated to have its own set of effective standards that contribute to revenue. From the perspective of other stakeholders, competition has driven significant variation in new approaches, moving away from consensus, as competing organizations, tool vendors, and consultants try to promote what they provide as differentiating for success in the industry. All of this has driven proliferation of standards over the years.
- Domains – A focused, narrow view often doesn't look beyond the domain for commonality.

Impact

The impact of this problem includes the following (Roedler 2010):

- Less effective or efficient processes that are not focused on leveraging commonalities or lessons learned from a wider base of practitioners. This causes redundancy and has resulted in incompatibilities and inconsistencies between the standards making it difficult to use them concurrently.
- Less effective solutions that are not focused on a common approach to solve a problem or need.
- Obstacles for communicating (at all levels), working in integrated teams, and leveraging resources.
- Stove-piping due to the incompatibilities and inconsistencies of and lack of leveraging commonalities.

Objective of Alignment

The objective is to make the standards more usable together by achieving the following (Roedler 2010):

- common vocabulary
- common concepts that account for differences such as domains
- single, integrated process set
- single process structure
- jointly planned level of prescription
- suitability across multiple audiences
- inclusion of considerations in a wide range of domains and applications
- inclusion of guidance for tailoring and adaptation to account for project specific needs and differences

Alignment of Systems Engineering Standards

Approach

A collaborative effort has been in place for the past two decades that includes ISO/IEC JTC1/SC7 (Information Technology, Systems and Software Engineering), the IEEE Computer Society, the International Council on Systems Engineering (INCOSE), and others. A collaborative process is being used to align the standards. This process is built around a foundational set of vocabulary, process definition conventions, and life cycle management concepts provided in ISO/IEC/IEEE 24765 (Vocabulary), ISO/IEC/IEEE 24774 (Specification for process description), and ISO/IEC/IEEE 24748-1 (Guide to Life Cycle Management), respectively. At the heart of the approach is the alignment of ISO/IEC/IEEE 15288 (System life cycle processes) and ISO/IEC/IEEE 12207 (Software life cycle processes), which provide the top-level process framework for life cycle management of systems and software. This enables concurrent and consistent use of the standards to support both systems and software life cycle management on a single project. The approach includes the development or revision of a set of lower level supporting standards and technical reports for elaboration of specific processes, description of practices for specific purposes (e.g., systems/software assurance), description of artifacts, and guidance for the application of the standards.

Past Accomplishments

INCOSE, IEEE, ISO, and other SDOs and industry associations have collaborated to align the key SE related standards and resources to be consistent and to manage their evolution to enable concurrent usage. Figure 2 shows ISO/IEC/IEEE 15288 is at the center of this Co-evolution model (Roedler 2023). This is due to it serving as the initial basis for leveraging terminology and concepts as a baseline. As part of this alignment effort, INCOSE adopted the ISO/IEC/IEEE 15288 process set, definitions, and terminology for shaping the system life cycle process information in the INCOSE SE Handbook in 2006. As the Systems Engineering Body of Knowledge (SEBoK) started its development in 2009, the project team also adopted ISO/IEC/IEEE 15288 and the INCOSE SE Handbook as key resources for guiding its content. Each of these resources have their unique purposes and scope, but have found utility in aligning. Over time the three resources, shown as a set of three key resources in the middle of the figure, have reached a point where each influences the other. In turn, these resources have been a catalyst for alignment of the other SE related documents shown.

As part of the alignment effort, ISO/IEC JTC1/SC7 formed a Life Cycle Process Harmonization Advisory Group that evaluated the standards for systems and software engineering. The objective of the group was to provide a set of recommendations for further harmonization of the industry standards. Specifically, its charter included:

- Perform an architectural analysis and recommend a framework for an integrated set of process standards in software and systems domains.
- Making recommendations regarding the future content, structure, and relationships of ISO/IEC/IEEE 12207, ISO/IEC/IEEE 15288 and their guides, as well as other related SC7 documents.

The result of this work has been a well aligned set of system and software standards, as shown in the Taxonomy of SE Related Standards figure in the Systems Engineering Related Standards Landscapearticle.

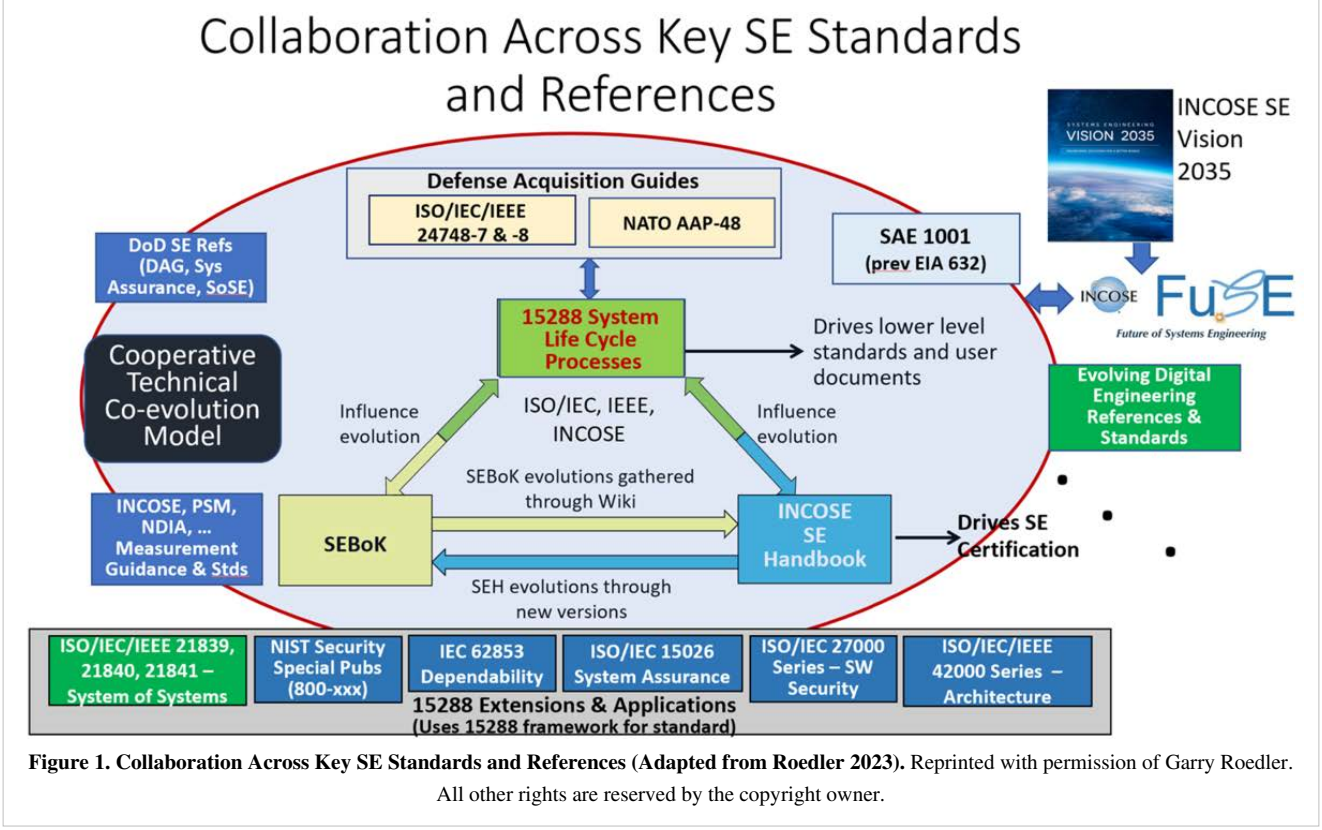

Figure 1. Collaboration Across Key SE Standards and References (Adapted from Roedler 2023). Reprinted with permission of Garry Roedler. All other rights are reserved by the copyright owner.

Current Efforts

The industry continues to harmonize SE related standards and references. The collaboration has grown to include the work of the organizations and projects shown in Figures 2 and 3. These organizations are working towards the goal of completing a complementary and supplementary set of systems engineering resources that use the same terminology, principles, concepts, practices, and processes and can be used concurrently without issues.

There are some current challenges that need to be considered as the SE standards continues to evolve. These include:

- Standards have a life cycle – development, publication, review, revision, withdrawal. Where the standards are in their life cycle influences how easily they can adapt to alignment efforts.
- It is hard to achieve commonality, since it is not always easy to determine where to start the harmonization. That is, which standards become the basis for the alignment. This determines what is impacted by changes.
- After more than two decades of harmonization efforts, the industry is still struggling with standards proliferation.
- Emerging topics are not necessarily in line with the core or existing standards.

These challenges will continue to be considered and addressed to form the best set of technical references possible.

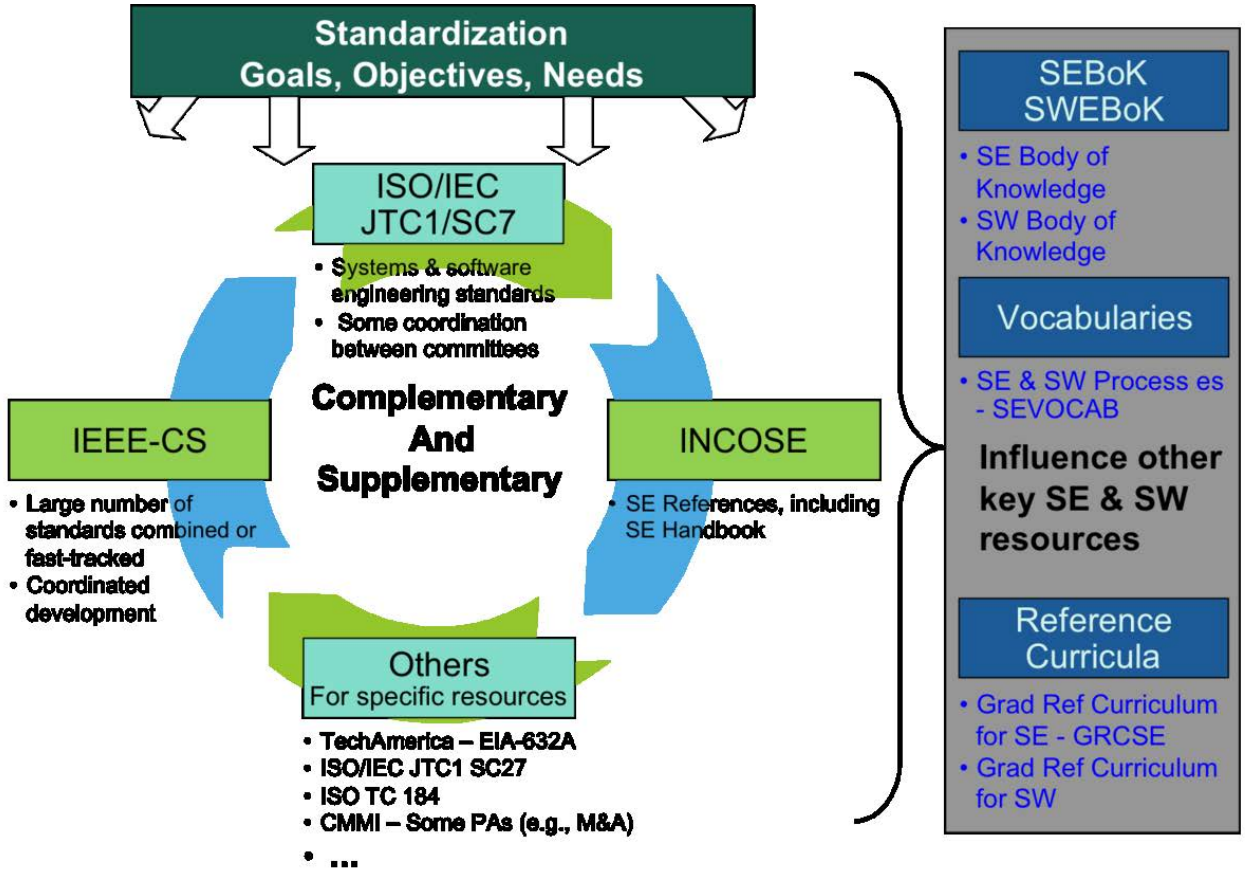

Figure 3. Growing Industry Collaboration. (Adapted from Roedler 2023). Reprinted with permission of Garry Roedler. All other rights are reserved by the copyright owner.

Practical Considerations

Key pitfalls and good practices related to systems engineering standards are described in the Systems Engineering Related Standards Landscape article.

There are also instances in which standards groups for program management, safety, or other disciplines create standards on topics addressed within systems engineering, but use different terminology, culture, etc. One such example is risk management, which has been dealt with by many professional societies from a number of perspectives.

Systems engineers must also be aware of the standards that govern the specialty disciplines that support systems engineering, as discussed in Part 6.

Finally, the challenges listed above under the Current Efforts are also reflective of some of the Pitfalls when trying to align the standards and references.

Application of Systems Engineering Standards

- Lead Author:
- Garry Roedler
- Contributing Authors:
- William Bearden, David Endler, and Mike Yokell

-

Standards can have an influence on organizations and their projects as indicated in Figure 1 (below). The standards provide sets of process, project, and product requirements and associated guidance that organizations use to influence the definition of their organization and project specific processes. Some pitfalls and good practices in utilizing standards are also identified in the article on Systems Engineering Related Standards Landscape. In this article, several additional factors related to the utilization of the standards in systems engineering (SE) are presented.

Standards and their Utilization

A standard is an agreed upon, repeatable way of doing something. It is a published document that contains a technical specification or other precise criteria designed to be used consistently as a rule, guideline, or definition. Standards help to make life simpler and to increase the reliability and the effectiveness of many goods and services we use, as detailed in Why Standards. Standards are created by bringing together the experience and expertise of relevant stakeholders, such as the producers, sellers, buyers, users, and regulators of a particular material, product, process, or service.

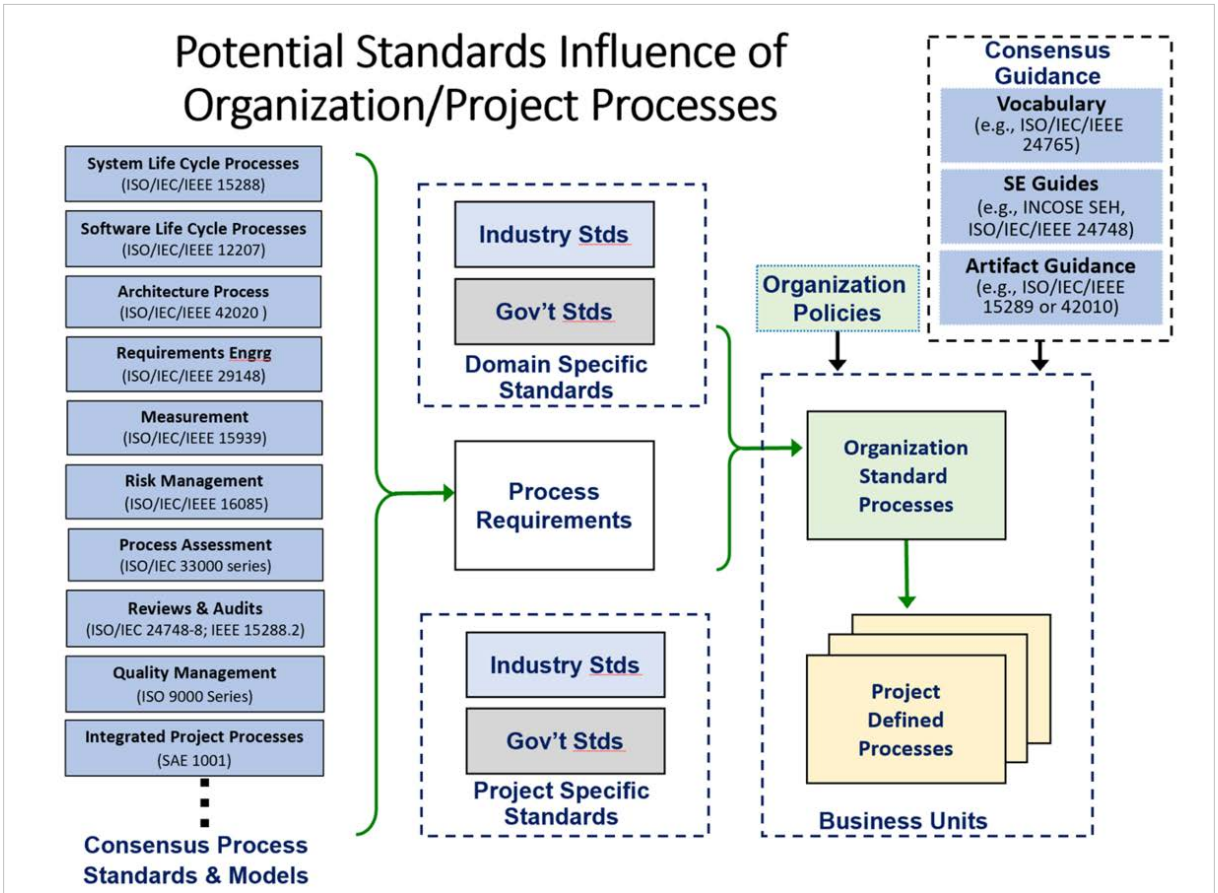

Figure 1. Potential Standards Influence of Organization and Project Processes (Adapted from Roedler 2011). Reprinted with permission of Garry Roedler. All other rights are reserved by the copyright owner.

Standards are designed for voluntary use and do not impose any regulations. However, laws and regulations may address certain standards and may make compliance with them compulsory.

Further, organizations and their enterprises may choose to use standards as a means of providing uniformity in their operations and/or the products and services that they produce. The standard becomes a part of the corporate culture. In this regard, it is interesting to note that the ISO/IEC/15288 (2023) standard has provided such guidance and has provided a strong framework for systems engineers, as well as systems engineering and business management, as forecast earlier by Arnold and Lawson (2004).

ISO directives [1] state the following:

> *A standard does not in itself impose any obligation upon anyone to follow it. However, such an obligation may be imposed, for example, by legislation or by a contract. In order to be able to claim compliance with a standard, the user (of the standard) needs to be able to identify the requirements he is obliged to satisfy. The user needs also to be able to distinguish these requirements from other provisions where a certain freedom of choice is possible. Clear rules for the use of verbal forms (including modal auxiliaries) are therefore essential.*

Requirements, Recommendations, and Permissions

In order to provide specificity, standards employ verb forms that convey requirements, recommendations, and permissions. For example, the ISO directives specify the following verb usages:

- The word *shall* indicates requirements strictly to be followed in order to conform to the standard and from which no deviation is permitted.
- The word *should* indicates that among several possibilities, one is recommended as particularly suitable without mentioning or excluding others, or that a certain course of action is preferred, but not necessarily required, or that (in the negative form) a certain possibility or course of action is deprecated but not prohibited.
- In the past, the word *may* indicates a course of action permissible within the limits of the standard. More recently, the use of *may* is not preferred for use in a standard and should be avoided. *Can* is the preferred term in most situations.

The directive also indicates that standards should avoid the use of *will*, *must*, and other imperatives. Futhermore, the use of the term *ensure* should be avoided, since it is rare that anything can be absolutely ensured. It reflects a guarantee. However, the phrase *help ensure* is acceptable.

Certification, Conformance, and Compliance

In the context of the management system standards (such as ISO 9001 or ISO 14000), certification refers to the issuing of written assurance (the certificate) by an independent external body that it has audited a management system and verified that it conforms to the requirements specified in the standard.

Typically, other more specific systems engineering standards are not the subject of certification. They are self-imposed in order to improve uniformity of organization and enterprise operations or to improve the quality of products and services. Alternatively, they may be dictated by legislation, policy, or as part of a formal agreement between an acquirer and a supplier.

In the context of engineering standards, compliance typically refers to adhering to mandatory legal or regulatory requirements, while conformance refers to adhering to voluntary standards or specifications. Compliance is often driven by external authorities, while conformance is often a company's internal commitment.

Conformance to standards is generally considered to be the voluntary action of an organization to meet the requirements or tailored requirements of a consensus standard or other guidance or specification. Many standards include a Conformance Clause that identifies what is required to make a claim of conformance or tailored conformance to the standard. This is especially true for engineering process standards.

Sometimes Conformance testing is a focus for product standards. Conformance testing, or type testing, is testing to determine whether a product or system meets some specified standard that has been developed for efficiency or interoperability. To aid in this, many test procedures and test setups have been developed either by the standard's maintainers or by external organizations, such as the Underwriters Laboratory (UL), specifically for testing conformity to standards.

Conformance testing is often performed by external organizations, which is sometimes the standards body itself, to give greater guarantees of compliance. Products tested in such a manner are then advertised as being certified by that external organization as complying with the standard. Service providers, equipment manufacturers, and equipment suppliers rely on this data to ensure quality of service (QoS) through this conformance process.

When compliance to a or more standards is needed, the agreement or contract has usually identified the standard(s) compliance as a requirement. Compliance with engineering standards is crucial for applications with a high need for safety, reliability, and functionality of products, systems, and infrastructure. It involves adhering to established rules, regulations, and best practices to meet industry requirements and legal obligations. Compliance is often enforced by external authorities, such as government agencies or industry bodies, and failure to comply can result in penalties or sanctions.

Key aspects of standards compliance include:

- Identifying and selecting the relevant standards that will be part of the agreement.
- Identifying and understand the applicable requirements of the standards.
- Integrating the requirements of the standards into the organization or project processes, product requirements, or project requirements with appropriate adaptation and tailoring; and documenting the incorporation and compliance demonstration needed.
- Verifying compliance through appropriate and valid means and documenting it.

Some challenges for compliance include:

- Keeping current – standards and other requirements can change, then requiring changes ot project planning and implementation, if a specific version is not part of the agreement.
- Balancing between compliance with standards and leveraging innovation in products or processes.
- Capturing and maintaining accurate documentation of the compliance can require structured and ongoing data management.

Tailoring of Standards

Since the SE standards provide guidelines, they are most often tailored to fit the needs of organizations and their enterprises in their operations and/or for the products and services that they provide, as well as to provide agreement in a contract. Tailoring is a process described in an annex to the ISO/IEC/IEEE 15288 (2023) standard. ISO/IEC/IEEE 15288 (2023) addresses the issues of conformance, compliance, and tailoring as follows:

- Full conformance, or a claim of full conformance, first declares the set of processes or other requirements for which conformance is claimed. Full conformance is achieved by demonstrating that all of the requirements have been satisfied using the outcomes or other criteria as evidence.
- Tailored conformance for processes uses the standard as a basis for establishing a set of processes and their requirements. However, the specific requirements are selected, excluded, or modified in accordance with the tailoring process. A clear statement is made regarding the scope of the claimed tailored conformance.
- The tailored text for which tailored conformance is claimed is declared. Tailored conformance is achieved by demonstrating that requirements for the processes, as tailored, have been satisfied using the outcomes as evidence.
- When the standard is used to help develop an agreement between an acquirer and a supplier, clauses of the standard can be selected for incorporation in the agreement with or without modification. In this case, it is more appropriate for the acquirer and supplier to claim compliance with the agreement than conformance with the standard, since the agreement usually becomes legally binding.
- Any organization (e.g., a national organization, industrial association, or company) imposing the standard as a condition of trade should specify and make public the minimum set of required processes, activities, and tasks which constitute a supplier's conformance with the standard.

Per ISO/IEC/IEEE 24748-2, “Life cycle models, as well as the processes from ISO/IEC/IEEE 15288, may be adapted for an individual project to reflect the variations appropriate to the organization, project and system while still being able to claim tailored conformance.”

ISO/IEC/IEEE 24748-2 provides an informational list of circumstances that influence tailoring.

Part 4 of the Guide to the SE Body of Knowledge (SEBoK) focuses on the application of systems engineering to the creation and life cycle management of various types of systems.

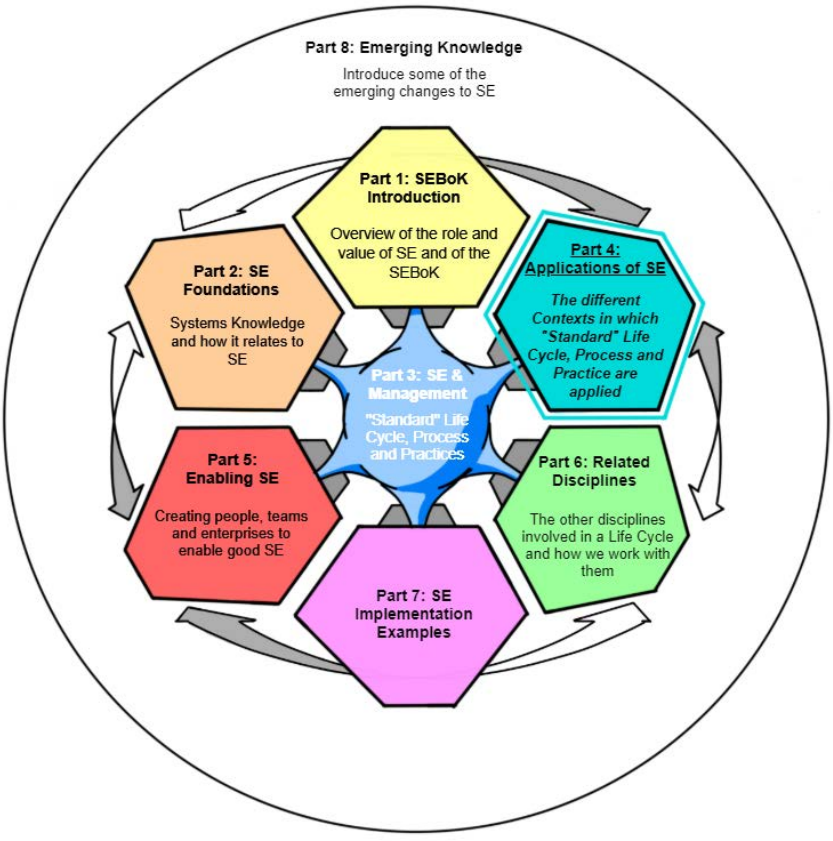

Figure 1 SEBoK Part 4 in context (SEBoK Original). For more detail see Structure of the SEBoK

In particular, the part covers product systems, service systems, enterprise systems, and systems of systems (SoS). It also contains a knowledge area describing Healthcare SE as a domain extension of these general SE approaches. This is the first of a number of planned domain-based extensions.

Knowledge Areas in Part 4

Each part of the SEBoK is divided into knowledge areas (KAs), which are groupings of information with a related theme. Part 4 contains the following KAs:

- Product Systems Engineering
- Service Systems Engineering
- Enterprise Systems Engineering
- Systems of Systems (SoS)
- Healthcare Systems Engineering

Systems Engineering Application

The different ways in which each of these contexts shapes the application of the generic SE Life Cycle and Process knowledge in Part 3 are discussed in detail in the KA above.

It is important to note that none of the contexts above are intended to be wholly separate or mutually exclusive from the others. They should be seen as overlapping and related frameworks which provide a starting point for how generic SE might be used to fulfil real world needs. We might think of each as a model of how SE can work in the real world. Each gives advice on how to use generic SE life cycle and process knowledge against its own viewpoint. If necessary, each may also develop new or extended knowledge relevant to its context, which becomes part of the extended toolkit of SE. Like any set of models, each has its own simplifications, strengths and weaknesses. As a general principle we would always select the simplest model available which fits the purpose and use that. For a complex outcome the combination of a number of models may be needed.

The real-world application of SE is no different. In most real projects, combinations of Product, Service, Enterprise and SoS knowledge may be needed to achieve success. The extent to which these combinations are taken from pre-determined approaches vs. the need for systems engineers to create such combinations as part of the application of SE is a key question for how SE is used. The final part of this knowledge, how SE is applied in the real world, sits within the knowledge base of the various application domain. Some domains have a very detailed set of procedures, guidelines and standards relevant to that domain, while others take general SE and apply it as needed using the judgement of those involved. In general, all domains have parts of both domain specific guidelines and experienced people. The SEBoK was originally written to be domain independent, other than through the application examples in part 7. To complete the SEBoK, we intend to create a series of Domain Application KA. These will give an overview of how SE application maps to domain practice. They are aimed at both the general SE reader who wants to know more about a domain and those working within a domain.

The Healthcare SE KA contained in this version of the SEBoK is the first such domain specific extension of the SEBoK.

This knowledge area is graciously sponsored by PPI.

Product systems engineering (PSE) is at the core of the new product development process (NPDP) that is needed to successfully develop and deploy products into different market segments. A market can be consumer based (e.g., private enterprises or general consumers) or it can be public (not-for-profit). Public markets address the strategic needs of a country or region, such as military, healthcare, educational, transportation, and energy needs. NPDP has two significantly overlapping and integrated activities:

1. **Systems engineering:** This includes concept generation, engineering design/development, and deployment
2. **Market development:** This includes market research, market analysis, product acceptance and market growth (diffusion), and rate of adoption

NPDP also includes manufacturability/producibility, logistics and distribution, product quality, product disposal, conformance to standards, stakeholder's value added, and meeting customer's expectations. The internal enterprise competence and capabilities such as customer support, sales & marketing, maintenance and repair, personnel training, etc., must also be taken into account.

Topics

Each part of the SEBoK is divided into knowledge areas (KAs), which are groupings of information with a related theme. The KAs in turn are divided into topics. This KA contains the following topics:

- Product Systems Engineering Background
- Product as a System Fundamentals
- Business Activities Related to Product Systems Engineering
- Product Systems Engineering Key Aspects
- Product Systems Engineering Special Activities

The Product Systems Engineering Background article discusses product types and the need for a product to be aligned with the business objectives of the enterprise. It also discusses the relationships between PSE, product development and technology development.

Various types of connections between product elements, and the concept of enabling systems are introduced in the Product as a System Fundamentals article. It also discusses product architecture, modeling, analysis, and integration with various specialty engineering areas.

Product launching and product offerings have close linkages to different business processes. The major linkages are to business development, marketing, product lines, quality management, project management, operations management, supply chain management, etc. These and other topics are described in the Business Activities Related to Product Systems Engineering article.

Products emerge when they are realized based upon a system definition. Realizing the system results in instances of the system that are either delivered as products to a specific acquirer (based upon an agreement) or are offered directly to buyers and users. Key Aspects of PSE are discussed in the Product Systems Engineering Key Aspects article, which discusses aspects such as acquired vs. offered products, product lifecycle and adoption rates, integrated product teams (IPTs) and integrated product development teams (IPDTs), product architectures, requirements and standards, etc.

The last article, Product Systems Engineering Special Activities, covers some of the special activities carried out by PSE during the different stages from concept through product deployment.

Key Terms and Concepts

Product

A product is an artifact that is created by some person or by some process such as a manufacturing process, software source code compilation and integration, building construction, creative writing process, or data processing.

In general, a business product is defined as a *thing produced by labor or effort*, or the *result of an act or a process*. It stems from the verb *produce*, from the Latin *prōdūce(re) (to) lead or bring forth*. Since 1575, the word *product* has referred to anything produced, and since 1695, the word *product* has referred to *a thing or things produced*.

In economics and commerce, products belong to a broader category of *goods*. The economic meaning of the word *product* was first used by political economist Adam Smith. In marketing, a product is anything that can be offered to a market that might satisfy a want or a need. In retail industries, products are called merchandise. In manufacturing, products are purchased as raw materials and sold as finished goods. Commodities are usually raw materials, such as metals and agricultural products, but a commodity can also be anything widely available in the open market. In project management, products are the formal definitions of the project deliverables that make up or contribute to delivering the objectives of the project. In insurance, the policies are considered products offered for sale by the insurance company that created the contract.

Product System

A product system is the combination of end products and the enabling products for those end products. This concept of a product system is illustrated in Figure 1. In the ANSI/EIA 632-2003 standard, just the term *system* is used, but the scope of the standard is clearly restricted to product systems.

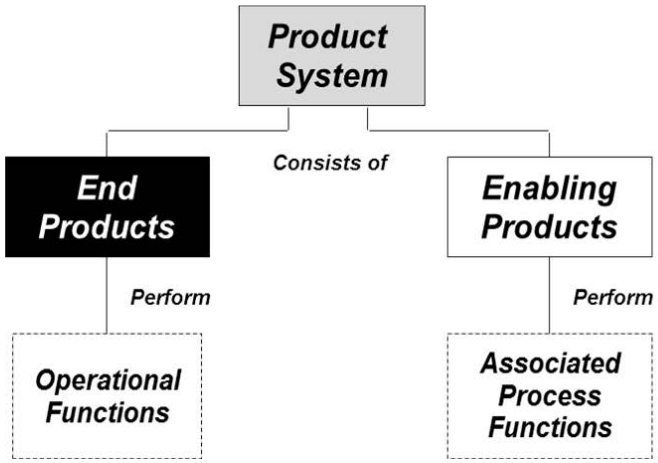

Figure 1. Product System Components (ANSI/EIA 632). Excerpts from "Processes for Engineering a System" (EIA-632), Copyright © (1999) TechAmerica. All Rights Reserved. Reprinted by Permission. All other rights are reserved by the copyright owner.

The end product can also be considered as a system with its own elements or subsystems, each of which has its own enabling products as illustrated in Figure 2. The product development process usually focuses only on the engineering of the end product. PSE is essential when the enabling products are by themselves complex or their relationship to the end product is complex. Otherwise, the use of a traditional product development process is sufficient.

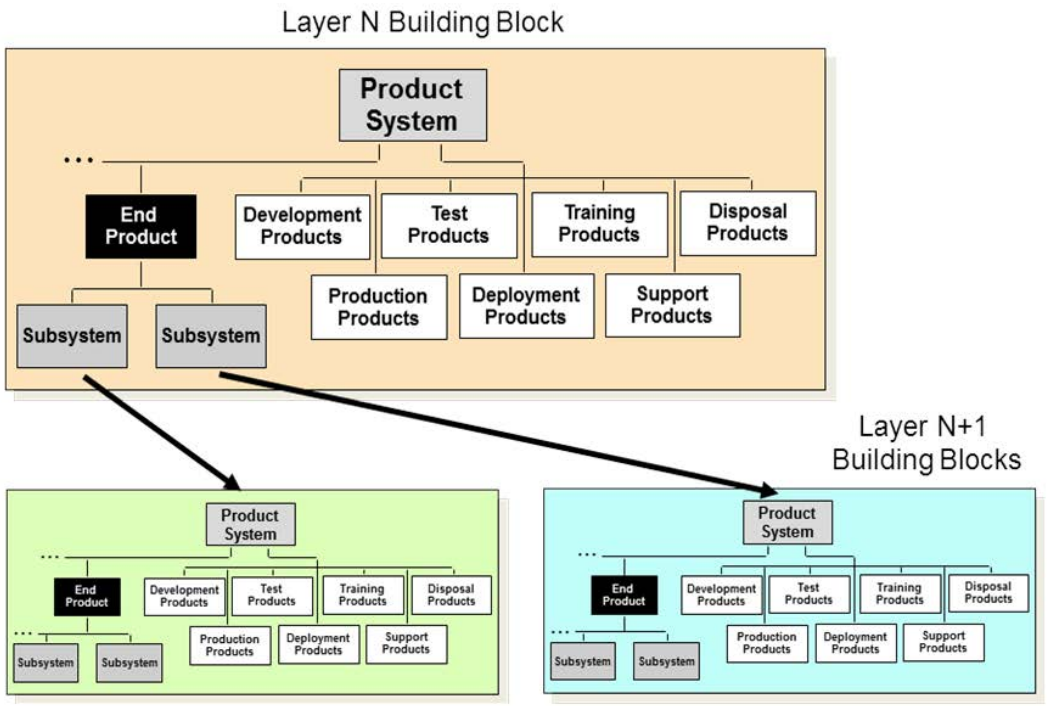

Figure 2. End Products and Enabling Products (ANSI/EIA 632). Excerpts from "Processes for Engineering a System" (EIA-632), Copyright © (1999) TechAmerica. All Rights Reserved. Reprinted by Permission. All other rights are reserved by the copyright owner.

Product Realization System

The product realization system is a related system that enables the *realization* of the product system. It consists of *all the resources to be applied in causing the Intervention System [i.e., the product system, in this case] to be fully conceived, developed, produced, tested, and deployed* (Martin 2004). Lawson (2010) refers to this as a respondent system in the system coupling diagram. The intervention system is the system that is to be realized (or conceived and brought into being) in order to address some perceived problem in the context as shown in Figure 3.

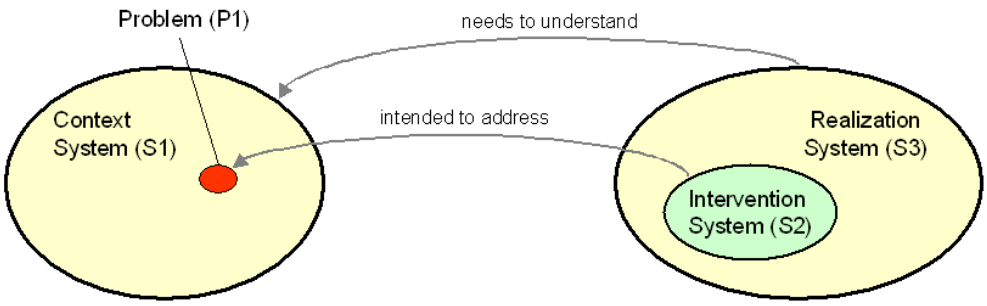

Figure 3. Realization System That Creates the Intervention to Solve a Problem (Martin 2004). Reprinted with Permission of Aerospace. All other rights are reserved by the copyright owner.

The realization system can be a service system (as described in knowledge area Service Systems Engineering) or an enterprise system (as described in the knowledge are Enterprise Systems Engineering). When the realization system is a service system, then the service could partially realize the system by just designing the product system without developing or creating it. This design service system can pass the design to a manufacturing service system that turns the design into a physical artifact. Usually an enterprise is established to orchestrate the disparate services into a cohesive whole that is efficiently and effectively performed to achieve the strategic goals of that enterprise.

The product realization system utilizes a product realization process as described in (Magrab et al 2010) or a product development process as described in (Wheelwright and Clark 1992).

Product Sustainment System

When the realization system delivers the product system into its intended environment, the product often needs a set of services to keep that product operational. This other system, when needed, is called the product sustainment system. It consists of various enabling products and operational services. The sustainment system in relation to the realization system and the deployed product system is illustrated in Figure 4. Notice that the realization may need to develop or modify the sustainment for the particular intervention (product) system under development.

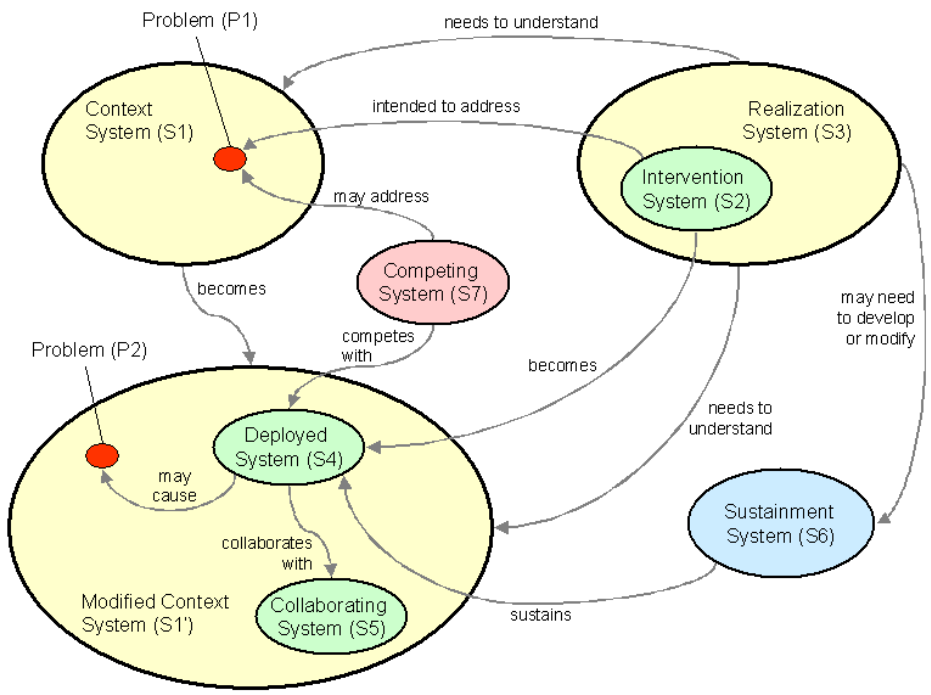

Figure 4. Product Sustainment System in Support of the Deployed Product System (Martin 2004). Reprinted with Permission of Aerospace. All other rights are reserved by the copyright owner.

Product Systems Engineering, Service Systems Engineering and Enterprise Systems Engineering

PSE is in line with Traditional Systems Engineering (TSE) as captured in most textbooks on the subject, such as Wasson (2006), Sage and Rouse (2009), and Blanchard and Fabrycky (2011). However, they do not cover the full breadth of PSE since they tend to focus on hardware and software products only. Other kinds of products to be engineered include personnel, facilities, data, materials, processes, techniques, procedures, and media (Martin 1997; Lawson 2010). Further discussions on the distinctions between the various kinds of products is provided in the Product Systems Engineering Background article. Product system domains could be data-intensive (e.g. transportation system), facilities-intensive (e.g. chemical processing plant), hardware-intensive (e.g. defense systems), or technique-intensive (e.g. search and rescue system). Most product systems are a composite of several different kinds of products that must be fully integrated to realize the complete value-added potential for the different stakeholders.

When compared to Service Systems Engineering (SSE) and Enterprise Systems Engineering (ESE), PSE has some unique considerations:

- Often a product is part of a product line where both the product line and the products that make up that product line must be engineered simultaneously.
- Products are often composed of parts and sub-assemblies produced by several suppliers. This entails the need to work closely with the supply chain to ensure a successful product offering.
- Large complex products often require a lengthy and complicated series of steps for assembly, integration and test. During integration, many of the key assumptions made during the initial product design could be challenged.

- Products will usually require certification as to their safety or other factors like energy conservation and environmental compatibility. Electronic products often require certification to ensure electromagnetic compatibility and limited electronic emissions into the radio frequency spectrum. Transportation products require certification for safe operations.
- Products often have a complicated distribution network since they are not always developed where the end user may require it. There could be depots, warehouses, multi-modal transportation, wholesalers, dealers, and retail stores as part of this distribution network. This introduces challenges in delivery, maintenance and support of the product.
- Products must be engineered along with the realization system and the sustainment system. Sometimes it is necessary to make tradeoffs between the features and functions of the product system, the realization system and the sustainment system.

These considerations and others will be addressed in the articles under this knowledge area. One of the responsibilities of ESE is to manage these various considerations across multiple product lines across the enterprise while maximizing profits and customer satisfaction. SSE is often dependent on the products resulting from the PSE. A service will often be based on a product infrastructure that includes elements like data processing, hardware, software, data storage, data entry devices, display devices, service delivery facilities and techniques, service desk technicians, maintenance personnel, service offering catalogs and printed materials. Each of these products in the service infrastructure may need to be separately engineered using its own PSE lifecycle.

Creating Value

An enterprise that creates products must also create value that exceeds the cost of the product in the eyes of the customer. This applies to both for-profit and not-for-profit private and public enterprises. The creation and delivery of products may be the result of an acquisition agreement or an offering directly to buyers or users. To remain competitive, enterprises also need to understand the effects of the global economy, trends in industry, technology development needs, effects of new technology breakthroughs, market segments creation and their expectations, and most importantly, ever evolving customer expectations.

Ring (1998) defines a system value cycle with three levels that a systems approach must consider to deliver real world benefit:

1. stakeholder value
2. customer need
3. system solution

Value will be fully realized only when it is considered within the context of time, cost, and other resources appropriate to key stakeholders.

Aligning product characteristics with associated operational activities

The user of a product views the product as an asset that can be utilized in one's own systems of interest (Lawson 2010). Thus, in supplying the product, the expected form of operation becomes a driving factor in determining the characteristics of the product. In several contexts, in particular for military related products, the desired operational activities are termed concept of operations (ConOps) and in the case of commercial enterprises the intended use of the system is described through some form of *Market Service Description* of the product. The intended use of the product is market/customer driven and so the product characteristics must be aligned with the operational intent.

Architectures as basis for value assessment

Architectures can be used by enterprises to shift product development from individual products to an underlying product line architecture that incorporates the flexibility required by the enterprise to rapidly tailor new technologies and features to specific customer requirements (Phillips 2001). In determining the architecture of the product system, various alternative designs may arise. Each of the architecture alternatives is to be evaluated with respect to its value contribution to end users and other stakeholders.

Role of evaluation criteria in selection between product alternatives

In assessing the product system value, one must consider the measures that are to be used to determine the *goodness* of the product alternatives (alternative architectures and technologies) with respect to producibility, quality, efficiency, performance, cost, schedule and most importantly, the coverage provided in meeting the customer's requirement or market opportunity.

Role of tradeoffs in maximizing value

The evaluation of alternatives must include the tradeoffs between conflicting properties. For example, in striving for superior quality and efficiency, tradeoffs must be made with respect to schedule and cost. See article on Measurement in Part 3. Tradeoffs are made during different stages of the development process: at the product or system level, at the subsystem and architecture definition level, and at the technology level (Blanchard and Fabrycky 2011).

There are a variety of methods for performing tradeoff analysis such as: utility theory, analytic hierarchical process, the Pugh selection method, multi-objective decision, multi-attribute utility analysis, and multi-variate analysis. For software, the Software Engineering Institute (SEI) provides 'The Architecture Tradeoff Analysis Method (ATAM)' (Kazman et al., 2000) for evaluating software architectures relative to quality attribute goals. ATAM evaluations expose architectural risks that potentially inhibit the achievement of an organization's business goals. The ATAM not only reveals how well an architecture satisfies particular quality goals, but also provides insight into how those quality goals interact with each other and how they trade off against each other.

Expanding role of software in creation of product value

Software has an increasing role in providing the desired functionality in many products. The embedding of software in many types of products (such as transportation vehicles, home appliance, and production equipment) accounts for an ever-increasing portion of the product functionality. The current trend is the development of a network of systems that incorporate sensing and activating functions. The use of various software products in providing service is described in the Service Systems Engineering knowledge area.

Product Systems Engineering Background

- Lead Author:
- Ricardo Pineda

-

The "Product Systems Engineering" knowledge area is graciously sponsored by PPI.

Product Types

A system is by definition composed of elements that interact. The system itself is usually an element of a larger system, and each element can often also be viewed as a system on its own.

A system element consists of one or more products. Products need to be produced or acquired. Some can be acquired or procured as-is, without need for fabrication or modification. Others need to be engineered, and in some cases, systems-engineered (Martin 1997). Basic product types are depicted in the figure below.

Types of products are not limited to hardware or software. Many other types of products perform functions necessary to meet stakeholder needs. Some are only relevant to certain industries or domains, such as structures for civil engineering, or ships for shipping or the naval domain. Systems engineers must remember not to allocate the required behavior for a system to hardware and software elements alone.

While we may associate the idea of a product with concrete objects like computer chip, phones, aircraft, or even command, control and communications centers, an organization or a process can also be a product. Sometimes a product is not complex enough to justify performing Product SE, and only needs product design engineering. Enterprise SE and Service SE should determine whether a product needs Product SE.

Product Taxonomy

For any system being developed, the systems engineers must decide what are the right elements to be included. This is not self-evident, because basic product types are not necessarily mutually exclusive. For example, some would consider that facilities contain hardware and people. Others would consider facilities to be separate from hardware and people. Some would include material as part of hardware, while others would not. Creating a taxonomy of product types can help the systems engineer think clearly and thoroughly about what components to include.

Business Objectives and Products

When it develops and launches a new product, an enterprise must align that product with its business goals, internal capabilities, and competition. It must align the end product with the systems expected to realize and sustain it.

The new product concept must be based on analysis that, besides product potential, also explores the ability of the enterprise to exploit that potential, including factors like organizational culture, focus, goals, and processes. Present and future markets and technology must be analyzed. So must several dimensions of competition: competitors' offerings and their plans, for entry into new markets and for product expansion including new functionality, features, or services. These, and the ability of the enterprise to react to them, must also be monitored for the enterprise to remain competitive in the long term.

Accelerating economic globalization since the 1970s has forced enterprises to respond to global needs, not just local or regional ones. Enterprises in the resulting hyper-competitive business environment must analyze their financial goals, their market positions, and the business segments in which they participate, in order to understand what products are required.

This is true for completely new products , product enhancements, penetration of new markets, and growth within existing markets.

Relationship between Product Systems Engineering and Product Development

Product development is the process of bringing a new product to market. Product SE (PSE) considers the complete product system–that is the product in the context of all its enabling elements. PSE takes a full life cycle perspective, “from cradle to grave” or “dust to dust.”

Technology-based product development may be thought of as coming from two sources. One, where innovation enhances existing technology, is aimed at relatively short-term market windows. The other involves long-term research to identify the technology developments required to realize the concept. These may be technologies whose availability is not foreseen in the near future, meaning that substantial investment and long lead times may be required before the proof of concept, initial operational capabilities (IOCs) or prototyping stages are reached, let alone the commitment to realize the actual product offering. Some authors claim that the systems engineering process and the new product development (NPD) process for this second source are one and the same.

It is from the second source that strategic initiatives (long-term applied research) realize new products in areas like military aircraft or bioengineering. When research resolves fundamental questions on matters of science or national/regional interest technology, breakthroughs occur.

This article concentrates on the first source of technology-based product development, that is, the one driven by ever-evolving market needs to enhance existing technology.

Product Development Patterns

When existing or near-future technology innovations are exploited to generate new product ideas, product development may follow any one of following scenarios (Phillips 2001):

- Product development may use well-established technologies to help the enterprise improve the efficiency of current operations.
- Product development may use well-established technologies to help the enterprise into new kinds of operations.
- Product development may use leading edge technologies to improve the efficiency of current operations.
- Product development may use leading edge technologies to help the enterprise into new kinds of operations.

The product itself may simply be a modification of an existing product or its presentation, it may possess new or different characteristics that offer additional benefits to the customer, and/or it may be entirely new and satisfy a newly-defined customer want or market niche (http:/ / www. businessdictionary. com/ definition/ product-development.html [1]).

Existing realization or sustainment systems may not be adequate to develop a given product. For example, it might be necessary to change development practices, use different testing methods or facilities, or upgrade manufacturing equipment and procedures. There might need to be improved customer support procedures and newly trained support personnel, upgraded maintenance facilities and tools, or modified spare parts delivery techniques.

Market Pressures

The product development process must be dynamic, adaptive, and competitive on cost, time-to-market, performance, and quality on a global scale. This is because in the global economy continuous technology innovation and constantly evolving markets and customer needs demand a rapid response.

Products themselves are often multidisciplinary in nature; product development must have close participation, not only from the different specialty engineering fields (mechanical, electrical, industrial, materials, and so on), but also from the finance field to analyze the total cost of development (including production), marketing and sales to understand market behavior and acceptance, manufacturers and distributors, and legal and public relations experts.

All this has mandated enterprises to assess how they create their products and services. The result has been an effort to streamline the development process. One example of this is seen by the deployment of integrated product teams (IPTs) sometimes known as integrated product development teams (IPDTs).

Product Systems Engineering

Product systems engineering strives for the efficient use of company resources in order to achieve business objectives and deliver a quality product. Product systems engineering activities range from concept to analysis to design and determine how conceptual and physical factors can be altered to manufacture the most cost-effective, environmentally friendly product that satisfies customer requirements. Engineering the product system requires an interdisciplinary approach that includes an analysis of the product and its related elements such as manufacturing, maintenance, support, logistics, phase-out, and disposal; these are all activities which belong to either the realization system or the sustainment system. The proper application of systems engineering and analysis ensures the timely and balanced use of human, financial, and technological assets, and technology investments to minimize problems, harmonize overall results, and maximize customer satisfaction and company profits.

Products are as diverse as the customers that acquire them and there are no universally accepted methods, processes, and technologies (MPTs) for end-to-end analysis of products and their supporting subsystems. Every product needs to adapt existing MPTs based on prior experiences and best practices, such as Toyota (Hitchens 2007), MITRE (Trudeau 2010), and NASA (NASA SELDP 2011). Product systems engineering helps develop the end-to-end analysis of products and sub-systems by performing the following tasks:

- determining the overall scope of needs for the product system;
- defining product and system requirements;
- considering all interactions between the different elements of the product system;
- organizing and integrating engineering disciplines; and
- establishing a disciplined approach that includes review, evaluation and feedback, and ensures orderly and efficient progress.

Constantly evolving needs and requirements, along with constant technology innovations, may render a committed product development obsolete even before deployment. This has led to debate among systems engineering professionals on the need for the systems engineering process to become more rapidly adaptable. Platform-based solutions to resolve some of these challenges (infrastructure as a service, platform as a service, and software as a service) are being studied and proposed (MITRE 2010; Boehm 2010).

Integrated Product Development Process

The integrated product development process (IPDP) starts with understanding market needs and developing a strategy that creates products that satisfy or exceed customer expectations, respond to evolving customer demands, adapt to changing business environments, and incorporate systems thinking to generate novel ideas and co-create value with extensive stakeholders' participation. IPDP is a continuously evolving process that strives to realize products whose cost, performance, features, and time-to-market help increase company profitability and market

share. Magrab, et al. (2010) discussed the IPDP in terms of four different stages; Figure 1 provides a snapshot of an IPDP and the main tasks carried out at each stage.

Stage I: Product Identification

During the product identification stage, the enterprise aims to identify an enterprise-wide strategy that flows down to individual product strategies resulting in a good business investment for the company. During this stage addressable markets for the product are identified in addition to geographical coverage of the product. The developments through this stage result in demonstration of strong customer need, determination of potential markets and geographic scope, the fitness of enterprise core capabilities to the product strategy, business profitability (return on investment, profit & loss), etc.

During this stage an integrated product team (IPT) first develops the IPDP for the project, usually by tailoring a corporate IPDP standard. The IPT assesses required technology innovation, feasibility of existing technologies, estimated time and cost of technology development, and the risks associated with markets, finances and technologies risk, etc. This stage also takes into account inputs from the continuous improvement (CI) process to develop new features and enhancements in existing products to address new market needs or customer demands.

Stage II: Concept Development

The main goal of the Concept Development stage is to generate feasible concepts for the potential product and develop MPTs that will satisfy the product's performance goals of economic viability and customer satisfaction. These concept designs must ensure that the company's core competencies can satisfy the requirements to produce the products while taking into account the market viability, manufacturability, and technical feasibility through an extensive analysis of alternative process.

During this stage SE supports the IPT in identifying different operational scenarios and modes of operation, functional requirements of the products, technology and performance risks, and the main components of the products and required interfaces among them, etc. This stage involves a highly interactive and iterative exchange of concepts among several IPTs and, depending on complexity of the products, a Systems Engineering Integration Team may be required to ensure analysis of all the possible solutions. During this stage inputs from the CI process helps analyze new technologies/processes including upgrades to existing technologies and create products that result in enhanced customer experiences.

Stage III: Design and Manufacturing

During the design and manufacturing stage the actual product is realized and manufactured. This stage starts with creating engineering drawings for the product, product configuration items specs, "design for X" (DFX), manufacturing design plans, production plans and schedules, test production run to ensure that the product meets customer requirements and quality criteria, and a plan for full production, logistics and distribution.

During this stage the product design & manufacturing engineering team works closely with operations managers to create MPTs to manage the technical effort for the product from an end-to-end perspective. Some of the SE activities during this stage include product integration, verification and validation plans; modeling, simulation, test & evaluation of the product system under critical scenarios; launch readiness plans including end-user test plans, operational readiness, etc. During this stage MPTs are developed and documented for proper handling of defective parts, processes, or functionalities. The CI process inputs include product and process performance enhancements and sustained life-cycle operations support.

Stage IV: Product Launch

During the product launch stage, the product is delivered to its potential markets. During production and deployment, MPTs are developed to ensure that the product meets its quality goals, satisfies customer requirements, and realizes the business plan goals. This requires provisions for customer care, logistics, maintenance, training etc., and a CI process to monitor product and product system technical performance and product quality. The CI process is realized through extensive data collection using customer satisfaction surveys and remotely or manually observing, recording, and analyzing process performance metrics, technical performance measure, quality metrics, etc.

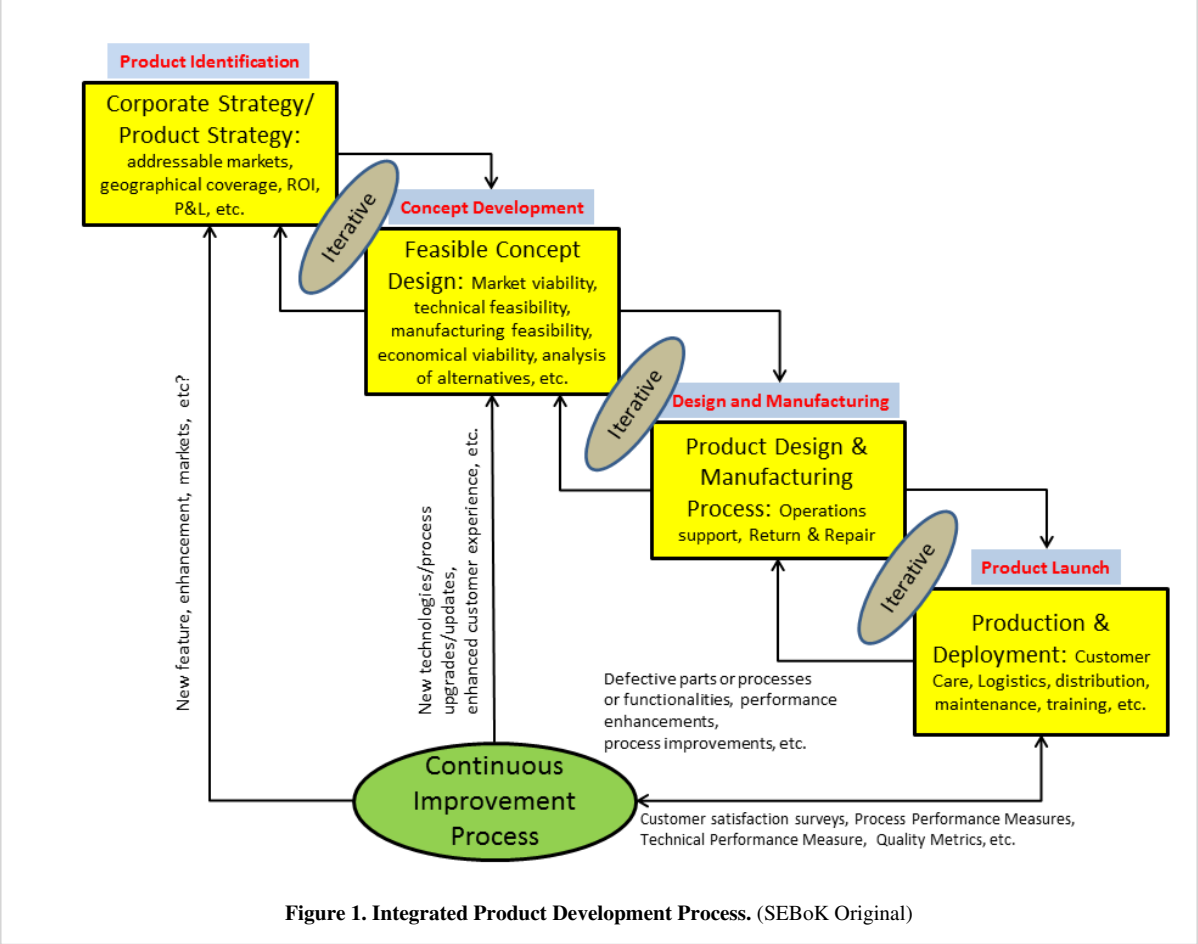

Figure 1. Integrated Product Development Process. (SEBoK Original)

Relationship between Product Systems Engineering and Technology Development

As technological advancement accelerates, product life cycles become shorter, especially for high technology products. As a result, enterprises risk having outdated or obsolete products that have lost pace with markets trends, technology trends, or customer expectations.

Product systems engineering should bring awareness of technology changes and trends to the analysis of new product ideas or innovations. This affects the time and cost inputs into the technical feasibility analysis of the product. The result should include a road map of required technology developments, which is then used to create the overall road map for the new product offering.

In these cases, new product ideas impose requirements on new technology developments.

On the other hand, when technology developments or breakthroughs drive product innovation or the generation of new markets, the technology developments may also generate requirements on product features and functionalities. Factors which dictate decisions about introducing products include the technology readiness levels (TRL), the integration readiness levels (IRL), the manufacturing readiness levels (MRL), the system readiness levels (SRL), and

the operational readiness of the enterprise to launch the product system. See the "Readiness Levels" section in the Product Systems Engineering Special Activities article.

Understanding the entities (i.e., components or elements) that compose the product is not a trivial task for systems engineers. It is not unusual for a new product to require developments in several technologies, including new materials, electronic components, software, maintenance and repair procedures, processes, or organizational structures. All of these developments must be factored into the IPDP for the successful deployment and proper use of the product.

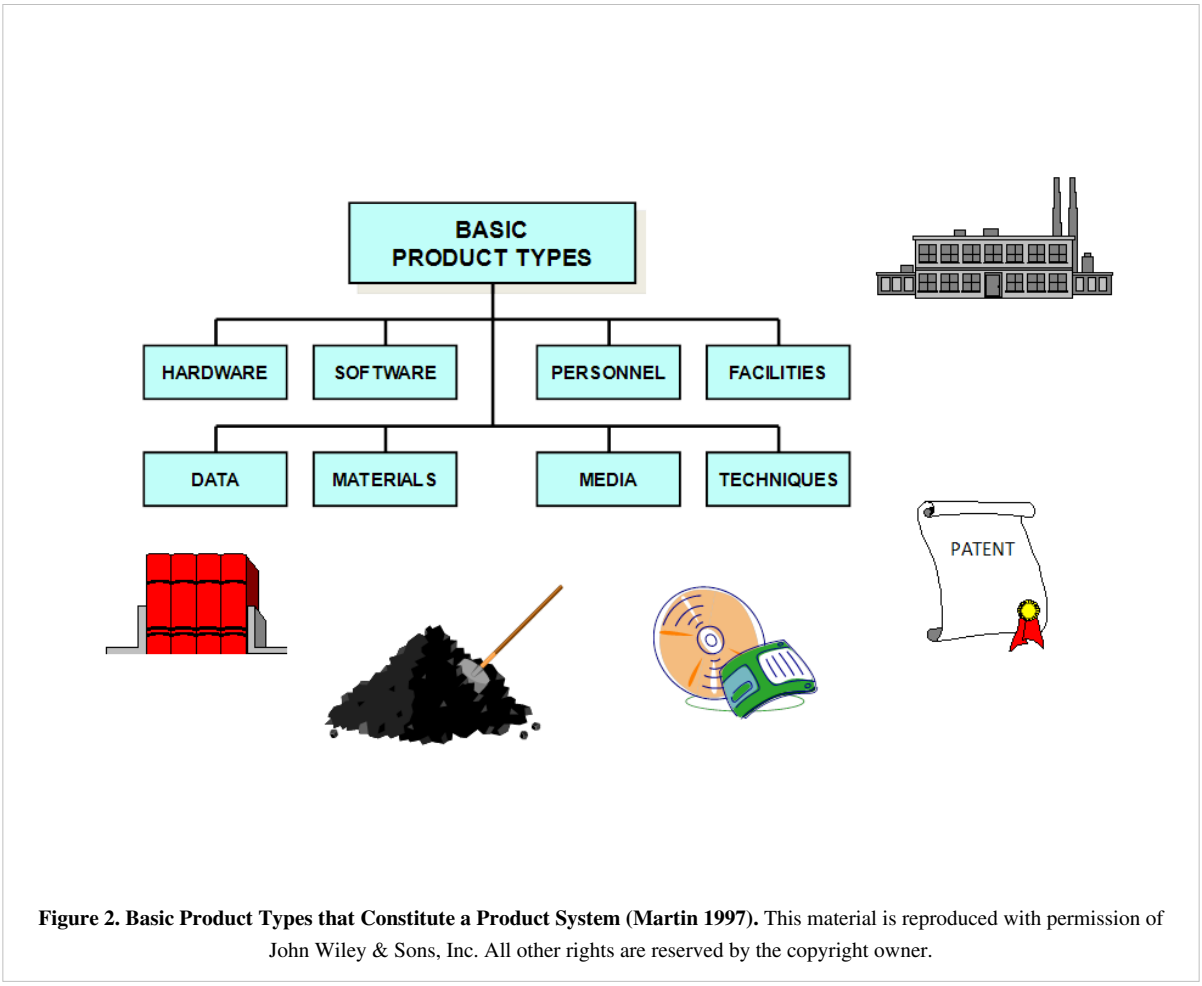

Figure 2. Basic Product Types that Constitute a Product System (Martin 1997). This material is reproduced with permission of John Wiley & Sons, Inc. All other rights are reserved by the copyright owner.

Product Type Examples

Examples of each product type are shown below (Martin 1997).

Table 1. Product Types (Martin 1997). This material is reproduced with permission of John Wiley & Sons, Inc.

Type	Examples
Hardware	Computer processor unit, radar transmitter, satellite payload, telephone, diesel engine, data storage device, network router, airplane landing gear
Software	Computer operating system, firmware, satellite control algorithm, robot control code, telephone switching software, database application
Personnel	Astronaut, computer operator, clerk, business executive, Laika (the cosmonaut dog), bus driver, cashier, maintenance technician
Facilities	Space rocket launch pad, warehouse building, shipping docks, airport runway, railroad tracks, conference room, traffic tunnel, bridge, local area network cables
Data	Personnel records, satellite telemetry data, command and control instructions, customer satisfaction scores
Materials	Graphite composite, paper, gold, concrete, stone, fiberglass, radar absorption material, cladded metals, integrated circuit substrate, magnetic memory core
Media	Data storage media (tape, disc, memory card), signal transport media (twisted pair wire, fiber optic cable, RF spectrum), communications media (television, radio, magazines), social media (blogs, Twitter, Facebook)
Techniques	Soldering, trouble trick response process, change notice handling, telephone answering protocol, project scheduling, data sorting algorithm

Materials could be thought of as basic raw materials, like steel, or as complex materials, like cladded metals, graphite composites, or building aggregate material. Personnel are not normally thought of as a "product," but that can change depending on the type of system in question. The National Aeronautics and Space Administration (NASA) space program "system" certainly produces astronauts. When personnel are considered product(s), it is not usually possible to simply find and hire personnel with the requisite knowledge, skills, and experience. These personnel "products" can often be developed using a product SE approach (Martin 1996). For example, you could specify requirements (i.e., required knowledge, skills, and experience) for each person that is part of the system. Interfaces can be specified for each person, and an assessment can be made as to the maturity of each person (i.e., each potential product). These are a few examples of how product SE can be applied to personnel products.

In enterprise systems engineering, we may need education and training systems to make up a part of our personnel system in order to produce people with the right competencies and capabilities.

Product as a System Fundamentals

- Lead Author:
- Ricardo Pineda

-

This article introduces fundamental concepts of product systems.

The "Product Systems Engineering" knowledge area is graciously sponsored by PPI.

Product Elements and Connections

Product systems consist of product elements and two kinds of connections: connections among elements, and connections between elements and things in the system environment. That portion of the environment that can be influenced by the system or that can influence the system is called the “context.”

Connections between elements contain interactions and relationships (Hybertson 2009). A connection is more than a mere interface.

Interactions occur across *interfaces* between the elements inside or outside the system, and can be defined as exchanges of data, materials, forces, or energy. Connections with an interactive nature can be represented in various engineering artifacts: schematic block diagrams, data flow diagrams, free body diagrams, interface control diagrams, port specifications, energy transfer diagrams, and so on. Product systems engineering (PSE) usually defines interactions in an interface control document, interface design document, interface requirements document, or the equivalent.

Connections also encompass relationships between elements. These relationships can be spatial, motion-related, temporal, or social.

Spatial relationships:

- one element is underneath another
- two elements are *x units* apart
- one element is inside another

Motion-related relationships:

- the relative velocity of two elements is *v units*
- the relative acceleration between two elements is *a units*

Temporal relationships:

- one element exists before another
- two elements must exist at the same time
- two elements must be separated in time by *t units*

Social relationships:

- a human element feels a particular way about a system
- a human element owns another (non-human) element
- a human element understands the operation of a system in a particular way

Relationships that are not about time can still change over time. For example, an element that is inside another element during one mode of operation can be outside of it during a different mode of operation. Therefore, one should not assume that non-temporal relationships are necessarily static in time.

Relationships can be represented in engineering artifacts, including the timing diagram, timeline diagram, mission reference profile, capability road map, and project schedule chart.

Social relationships include the implicit or explicit social obligations or expectations between the roles that human elements play in a system. These roles may be assigned different authorities, responsibilities, and accountabilities. See the discussion on organization behavior in the article Team Dynamics. Organizational behavior theories and human factors may need to be considered when engineering such a product system.

There can also be social relationships between the humans and the non-human elements of the system. This may involve how the human “feels” about things in the system or perhaps even the system as a whole. Humans inside or outside the system-of-interest may have different degrees of “understanding” with respect to how the system operates, its limitations and capabilities, and the best way to operate it safely and effectively. The “ownership” relationship can be important in determining things like who can operate or change some configuration or mode of the system.

There are many such social relationships in a product system that are often ignored or misunderstood when performing PSE. Social relationships can affect the overall performance or behavior of a product system to the point of determining its success or failure.

Core Product and its Enabling Products & Operational Services

A variety of systems (themselves being products or services) enable the development, delivery, operation and eventual disposal of a product, as shown in Figure 1. The concept of enabling systems is defined in the ISO/IEC 15288 standard (2015).

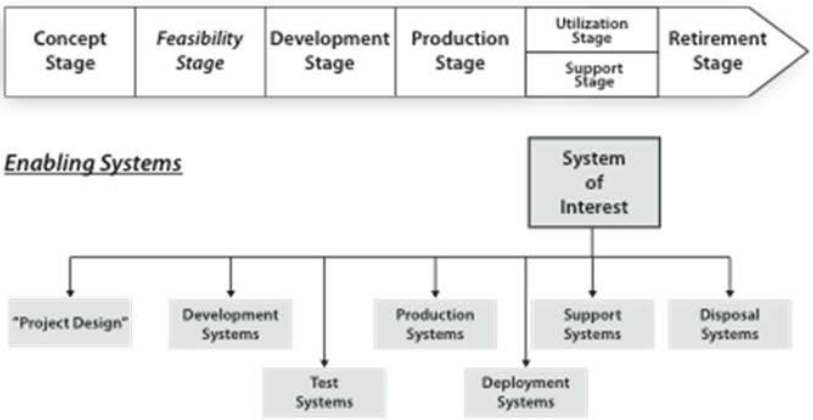

Figure 1. Example of Enabling Systems (Lawson 2010). Reprinted with permission of Harold "Bud" Lawson. All other rights are reserved by the copyright owner.

In the figure, the system-of-interest (SoI) goes into operation as a delivered product or offered service in the utilization stage while maintenance and logistics are provided (by a product sustainment system) simultaneously in the support stage. These two stages are commonly executed in parallel, and they offer opportunities to observe any need for changes in the properties of the product or service or how it is operated and supported. Making changes iterates the life cycle and results in new or improved products or features.

The delivered product and its enabling systems collectively form a wider system-of-interest (WSOI). The project design enabling system is an enterprise based system asset that establishes the strategy and means of organizing the projects to be executed along the life cycle. In many larger organizations, this type of enabling system is institutionalized and can be based upon recommendations of the Project Management Institute (PMI).

Product systems should be viewed as enabling service systems. That is, once deployed, a product system provides a service that contributes to an enterprise's operations. To the acquirer, the SoI provides operational services to users. This is true at several levels:

- Hardware and software products are used to enable the provisioning of service systems,
- Enterprises incorporate products as system assets and use them to enable operations, and
- Provided products are integrated into the system of systems.

Product Architecture, Modeling, and Analysis

IEEE standard 1471-2000 defines architecture as "the fundamental organization of a system embodied in its components, their relationships to each other, and to the environment, and the principles guiding its design and evolution" (IEEE 2000). Similarly, ISO/IEC 42010-2011 defines architecture as "fundamental concepts or properties of a system in its environment embodied in its elements, relationships, and in the principles of its design and evolution" (ISO/IEC 2011).

A product's purpose (stakeholder's need) is realized by a product system (the SoI). Because product systems are composed of different entities (components, assemblies, subsystems, information, facilities, processes, organizations, people, etc.) that together produce the results unachievable by any of the entities alone, architecting the product is based on a whole systems approach. To architect with a whole systems approach means to define, document, design, develop, manufacture, distribute, maintain, improve, and to certify proper implementation of the product's objectives in terms of the functional (the "what"), the behavioral (the use, or intended operations), the logical (interaction and relationships between entities) and the physical constructs (Wasson 2006; Maier 2009; Blanchard and Fabrycky 2011).

The system architect starts at the highest level of abstraction, concentrating on needs, functions, systems characteristics and constraints (concerns) before identifying components, assemblies, or subsystems. This is the systems view, and it is used to represent the stakeholder's market service description or the concept of operations (understanding of the opportunity/problem space).

Next to be documented, as needs become better understood, are architectural descriptions at different levels of abstraction, representing various stakeholders interests. These are the architecture models. They define the possible solution spaces for the product purpose in the form of detailed system, operational, behavioral, and physical requirements of the product system.

Different modeling techniques are then used to analyze different types of requirements. For operational scenarios and different modes of operation, there are hierarchical decomposition and allocation, architectural block diagrams (ABD), functional block diagrams (FBD), functional flow block diagrams (FFBD), and use case diagrams. For interactions and relationships among hardware and/or software components there are sequence diagrams, activity diagrams, state diagrams, and data flow diagrams. See (Maier 2009) Chapter 8 for an introduction to models and modeling.

Analysis of the solution space makes it possible to produce detailed technical specs, engineering drawings, blueprints, software architectures, information flows, and so on, that describe the entities in the product system. An entity's requirements bound its attributes and characteristics, levels of performance, operational capabilities, and design constraints. During design and integration, entity characteristics can be traced back to requirements (requirements traceability being a key aspect of SE). Verification and validation plans created during the requirements phase are the basis of testing certification that the product does what it was intended to do.

Overall, what occurs is the transformation of a set of requirements into products and processes that satisfy the stakeholder's need. The architecture is represented by a set of models that communicate an integrated view of the product's intent and purpose, and the interactions and interfaces required among all the different participating entities. The product's purpose is articulated in terms of business objectives (market, cost, functionality, performance, and time to deliver). The set of models includes sufficient variety to convey information appropriately to the stakeholders, designers/developers, specialty engineering, operations, manufacturers, management, and marketing and sales personnel.

Different architecture frameworks have been developed to guide product teams in defining the product architecture for commercial and for public enterprises. In general, an architecture framework describes a "view," meaning a "collection of models that represent the whole system from the perspective of a set of related stakeholder concerns." Prime examples of architecture frameworks are the Zachman framework (Zachman 1992), The Open Group

Architecture Framework (TOGAF) (TOGAF 2011), the Enhanced-Telecom Operations Map (e-TOM), just to mention a few in the commercial sector. In the case of public enterprises a few architecture frameworks include the Department of Defense Architecture Framework (DODAF 2.0) (DoD 2010), the Federal Enterprise Architecture Framework (FEAF) (FEA 2001), the British Ministry of Defense Architecture Framework (MODAF) (MOD 2004), etc.

Differences between acquired products and offered products play an important role in defining product system requirements. Acquired products are life cycle-managed directly by the acquirer; for instance, acquired defense systems are defined, developed, tested, owned, operated, maintained and upgraded by the defense agency. See the article Product Systems Engineering Key Aspects within this KA.

Specialty Engineering Integration

The INCOSE *SE Handbook* defines specialty engineering as:

"Analysis of specific features of a system that requires special skills to identify requirements and assess their impact on the system life cycle."

Areas of expertise that fall under this umbrella definition include logistics support, electromagnetic compatibility analysis, environmental impact, human factors, safety and health analysis, and training. The unique characteristics, requirements, and design challenges of a system-of-interest all help determine the areas of specialty that apply.

A number of specialty engineering areas are typically important to systems engineers working on the development, deployment, and sustainment of product systems. For example, logistics support is essential for fielded product systems that require maintenance and repair. The delivery of services, materials, parts, and software necessary for supporting the system must all be considered very early in the development activity. These factors should usually be

considered before the system requirements and concept definition are complete. To integrate these specialty disciplines sufficiently early on, the systems engineer needs to know what specialties relate to the system under development, how they relate to the systems engineering process, and how to integrate them into the life cycle process.

For product systems with significant hardware content and that operate in challenging environments, the following specialty engineering areas must usually be considered:

- manufacturability,
- reliability and maintainability,
- certification (essential where human safety is an issue),
- logistics support,
- electromagnetic compatibility (if they radiate),
- environmental impact,
- human factors,
- safety and health, and
- training.

The relationship of these specialty areas to the systems engineering process must be understood and considered. The key aspects of the relationship are:

- when the specialty needs to be considered,
- what essential data or information it provides,
- the consequences of not including the specialty in the systems engineering process, and
- how the systems engineers should interact with the specialty engineers.

Grady (2006) provides an overview, with references, for many of the specialty engineering disciplines, including reliability engineering; parts, materials, and process engineering (PMP); maintainability engineering, availability, producibility engineering, design to cost/life cycle cost (DTC/LCC), human factors engineering, corrosion prevention and control (CPC), system safety engineering, electromagnetic compatibility (EMC) engineering, system security engineering, mass properties engineering, and environmental impact engineering.

Eisner (2008) lists specialty engineering as one of the “thirty elements” of systems engineering. “Specialty engineering refers to a set of engineering topics that have to be explored on some, but not all, systems engineering efforts. In other words, some systems involve these special disciplines and some do not. Examples of specialty engineering areas include electromagnetic compatibility and interference, safety, physical security, computer security, communications security, demand forecasting, object-oriented design, and value engineering.” Some of what we consider specialty engineering in the present article, Eisner includes among his “thirty elements” of systems engineering, but not as part of the specialty engineering element.

There is no standard list of specialty engineering disciplines. What is considered specialty engineering varies according to the community to which the systems engineering belongs, and sometimes to the preferences of the customer.

Business Activities Related to Product Systems Engineering

- Lead Author:
- Ricardo Pineda

-

This topic discusses the interfaces between product systems engineering and other 'back office' and management activities that take place in an enterprise.

The "Product Systems Engineering" knowledge area is graciously sponsored by PPI.

Marketing, Product Life Cycle Management, & Quality Management

Product systems engineering (PSE) includes critical and robust interfaces with related business activities, such as marketing, product life cycle management (PLM), and quality. Traditionally, PLM has been a critical stage in the integrated product development process (IPDP) and continues to be an important tool for life cycle management after product deployment. PLM provides an important component of the PSE end-to-end view. The other component is the “breadth” component that captures everything relevant to the system at each life cycle stage. Recently, the focus has started to shift from the idea of managing just the life of the product, to an expanded view that includes the management of product-lines (families) or product platforms themselves. This provides an increase in sustainability, flexibility, reduced development times, and important reductions in costs as new or enhanced products are not launched from scratch every time.

PSE also includes interfaces with the marketing function; in particular, PSE works closely with the business and market development organizations to elicit product needs and intended operations in target markets to define product roll-out and possible phases of product introduction. Analysis of the market is critical during the entire product life cycle from conception through retirement with the understanding that each life cycle phase requires very different marketing approaches. During concept development, marketing has to help determine the potential market, the addressable market segments, define products, and product/innovations requirements for those markets. During the product introduction stage, marketing has to create demand and prompt early customers to try the product. During the growth and maturity phases, marketing has to drive public awareness, develop the brand, and differentiate the product and its features and feature releases to compete with new market entrants. During saturation, marketing must help manage diminishing volumes and revenues as focus shifts from top line (increased market share) to bottom line (increased production and distribution efficiencies) considerations. See the article on Procurement and Acquisition.

The links between PSE and quality are just as critical. The relationships between PSE and quality also reflect the broad view which includes the product and opportunity, but also the company’s internal goals, processes, and capabilities. Quality schemes which focus on a tangible product have been extensively used historically. More recent approaches that acknowledge and match PSE's holistic view have come into use. Issued during 1988, ISO 9000 is a family of standards which focuses on processes and the organization instead of the product itself. In addition, it calls out specific requirements for the design of products and services. ISO 9001 has served as a “platform” for many other schemes which are tailored to specific domains. A collaborative effort of the International Aerospace Quality Group, AS9100 contains all of the base requirements of ISO 9100 and expands further requirements which are critical and specific to the aviation, space, and defense industries. Similarly QS-16949 is a technical standard based on ISO 9001

but expanded to meet specific requirements in the worldwide automotive industry. PSE should play an important role in the design and implementation of any quality management system. See the article on Quality Management.

Capability Maturity Model Integrated (CMMI) for Development is a process improvement approach whose goal is to help organizations improve their performance. CMMI can be used to guide process improvement across a project, a division, or an entire organization. Although initially used in software engineering and organizational development, CMMI use is spreading to other domains since it provides organizations with the essential elements for effective process improvement. According to the Carnegie Mellon Software Engineering Institute, CMMI describe "an evolutionary improvement path from ad hoc, immature processes to disciplined, mature processes with improved quality and effectiveness." (SEI 2010).

Project Management & Business Development

The end-to-end view mandated by PSE requires strong relationships with project management and business development activities. The 'concurrent' thinking encouraged by PSE necessarily requires multiple projects to move forward in parallel, but with a high level of coordination. In this sense, PSE and project management (see Systems Engineering and Project Management) are two heavily intertwined disciplines which have been shown to generate synergy and added value for the stakeholders.

The systems engineering management plan (SEMP) is the key document covering the activities, milestones, organization, and resource requirements necessary to ensure the system-of-interest accomplishes its intended goals and mission. A key objective of the SEMP, which is usually developed during the conceptual design phase, is to provide the structure, policies, and procedures to foster the optimum management of projects and activities needed for system development and implementation (Blanchard and Fabrycky 2011).

An effective and agile PSE function can make important contributions to business development for an enterprise or company. The primary goal of business development activities is to identify new types of business/product/services which are believed to address existing or potential needs and gaps (new markets), to attract new customers to existing offerings, and to break into existing markets. PSE's end-to-end view of the life cycle can support market development by intelligence gathering, feedback on market acceptance or rejection, strategic analysis, and proposition development and campaign development. Finally, PSE should encourage the consideration of several factors within the new product development which may enhance market development. For example, in well-established companies, business development can often include setting up strategic alliances with other, third-party companies. In these instances, the companies may leverage each others expertise and/or intellectual property to improve the probability for identifying, researching, and bringing to market new businesses and new products. See (Sørensen 2012).

Supply Chain Management & Distribution Channel Management

PSE provides the following information to the supply chain management function in an enterprise:

- product specifications (including intended uses of the product),
- product acceptance criteria (for accepting delivery of the product from the supplier),
- product testing and qualification plans and procedures, including which ones are responsibility of the supplier and which ones are responsibility of the acquirer,
- interface specifications associated with each product,
- supplier certification criteria (including a list of pre-certified suppliers), and
- feedback on quality of products delivered by suppliers.

Supply chain management will, as necessary, manage the identification and certification of qualified suppliers with the concurrence of, and coordination with, systems engineering and product engineers.

PSE provides the following information to the distribution channel management function in the enterprise:

- product specifications (including intended uses of the product),
- product user manuals (including installation and maintenance documentation),
- product packaging (for safe delivery of product and for display in retail channels),
- product qualification data (to prove that product meets its design requirements),
- product certification data (to prove product is certified for safe and secure operation),
- user support instructions, and
- operator certification criteria.

Distribution channel management will, as necessary, manage the identification and certification of qualified distributors with the concurrence of, and coordination with, systems engineering and product engineers.

Capability Management & Operations Management

Capability is defined in various ways, but each definition is consistent with the notion of "the ability to do something useful." Products and services are acquired by end users to enable and improve their operational capability to let them do something useful, whether in a military context (e.g., weapon systems improve the capability to conduct effective military operations), or a social context (e.g., a car may improve the ability to satisfy the transport needs of a family). Users acquire products (e.g., military equipment, cars, “productized” service offerings from airlines and taxi companies, etc.) to contribute to satisfying their capability needs.

Capability management involves identifying and quantifying capabilities (existing, new, or modified) that will be needed to meet enterprise goals, as well as selecting a coherent set of product and services across all components of capability that will be integrated to provide the needed capabilities. So normally, requirements for "product systems" are derived from capability management. Capability management is likely to include trade-off processes to make the best use of existing products or low-risk evolutions of them, and conversely identifying when a capability need can only be satisfactorily met by a new-generation product, or even a new type of product altogether. In some cases, new offered products or disruptive technologies (e.g., jet engine, nuclear weapons, and internet) create opportunities for new or improved capabilities, in which case capability management focuses on ensuring that all needed components of capability are put in place to exploit the opportunity provided by the new product or technology. See Capability Engineering.

Operations management uses an integrated set of product systems to deliver value to the enterprise and its stakeholders. Operations management involves bringing new product systems into operation, normally while maintaining business continuity, so transition plans and relevant metrics are critical; next, operations management addresses some of the following: working up to full operational efficiency across all components of capability, coping with incidents, contingency plans to deal with major disruptions, adjusting the system to cope with new ways of working and to deliver new services to meet new enterprise requirements and accommodate new product systems entering service, and eventually planning transitions out of service or major in-service upgrades. PSE supports operations management by defining all dependencies for successful operation on other systems and services, and by providing ongoing engineering support for spares and repairs, obsolescence management, and system upgrades. Systems engineering in the in-service phase has been analyzed (Elliott et al. 2008) and is best viewed as the same basic systems engineering process conducted at a much higher tempo (Kemp and Linton, 2008) and requiring detailed understanding of constraints imposed by the current environment and usage. Configuration management and configuration status accounting during operation is very important for high value and high integrity systems to ensure that any changes are designed to fit the "as-is" system, which may be significantly different from the "as-originally intended" specification and design.

Product Engineering, Assembly, Integration, & Test

Product engineering typically results in an engineering model that is used as the "blueprint" for assembling, integrating, and testing (AIT) a product system. These AIT activities may be performed on prototype versions, as well as final production versions to be delivered to end users. There is significant experience in domain specific industries in performing AIT for complex products. Unfortunately, very little is written in the general literature. Wasson (2006) and de Jong (2008) cover some of these aspects. See also System Integration and System Verification.

For software products, the collection of code modules are integrated via some form of integration program (typically called "make"). The integrated modules are then subjected to tests to exercise the various potential paths through the software. Since software can be easily changed, it is common to use some form of regression testing based upon test suites in order to verify software correctness. Another common means of testing is by fault injection as described by Voas and McGraw (1998).

Manufacturing, Test, & Certification

Systems engineers usually work with manufacturing indirectly through the electrical and mechanical design teams. There are times in the development cycle when a direct interface and working relationship between systems engineering and manufacturing is appropriate and can improve the probability of program and system success. Early in the program the system concept must be examined to determine if it is manufacturable. The requirements and the concept design should be reviewed with the manufacturing engineers to obtain an assessment of the risks associated with the production of the system. If substantial risks are identified, then actions that improve the manufacturing capabilities of the organization, modify the design, and perhaps change the requirements may be needed to reduce the identified risks to acceptable levels. Manufacturing prototypes or proof of manufacture (POM) units may be necessary to reduce the risk and to demonstrate readiness to proceed with the design and the system development. Similarly, the systems engineers must establish that the system will be testable early in the product development phase. The requirements should be mapped to verification methods of inspection, analysis, demonstration, and test before they are released to the design team. All requirements mapped to test must be examined to determine the test methods and the risk associated with accomplishing the necessary tests as part of the product qualification, acceptance, and release process. Where risks are identified, the systems engineers must work with the test engineers to develop the necessary test capabilities.

Product Delivery & Product Support

Most products live much longer in the usage phase than in the development phase. The costs associated with product support are usually greater than the cost of developing the product. These two facts make it very important for the product systems engineer to consider the product delivery and support as part of the earliest activities during development. The design of the product dictates the maintenance and support that will be required. The systems requirements are the first means of influencing the design to achieve the desired product support. If maintenance, reliability, and support requirements have not been defined by the customer, then the systems engineer must define these to achieve the support methods and costs that the customer, users, and the organization responsible for support will find financially acceptable.

Product Systems Engineering Key Aspects

- Lead Author:
- Ricardo Pineda

-

The "Product Systems Engineering" knowledge area is graciously sponsored by PPI.

Acquired Products versus Offered Products

The emphasis for traditional systems engineering (TSE) is in the provisioning of products and related services that meet stakeholder needs and requirements. For acquired products, an acquirer specifies the needs and requirements, selects a supplier for development and provisioning, and then receives the needed products and services. The acquirer, after acceptance, usually owns, operates, and maintains the product and the support systems supplied by the developer. Offered products are provided by suppliers based on opportunities to develop and offer products and services to potential users of the product based on business objectives usually measured in terms of value addition to the stakeholder.

In the provisioning of product systems and related services, the enterprise owning and provisioning the product and services typically makes agreements with other suppliers to also provide elements, methods, and tools that are used during their entire life cycle. The supplying enterprises, in turn, may make further agreements with suppliers in regards to building a supply chain. The complexities of dealing with supply chains must be accounted for with respect to cost, risk, and schedule and thus can have an impact upon product or service maturity. (See articles under the Systems Engineering Organizational Strategy knowledge area (KA) in Part 5.)

Acquired Products

Specific needs for a product or service typically result in some form of an agreement between the acquirer and a supplier as specified in the agreement processes of ISO/IEC 15288 (2015). The acquirer specifies the need and requirements for the properties of the expected product or service and may or may not place specific requirements upon how the supplier plans to organize their life cycle treatment of the product or system.

The degree of formality involved with the agreement varies and is strongly influenced by whether the customer is a government entity or a commercial entity. Government contracts usually incorporate strict specifications and other unique requirements that are rarely found in commercial contracts. Government acquisition agents often specify design characteristics in addition to functional and performance specifications. Design specifications place constraints on product systems engineering (PSE) by explicitly defining the details of a product's physical characteristics. The government acquirer may also specify how the product is to be designed and developed or how it is to be produced. Government specifications tend to be longer, more detailed, and more complex than functional specifications and much longer than specifications used in a commercial environment.

When contracting with the government or similar enterprises, the PSE must identify disagreements related to the meaning of a particular provision in a contract, and work with contracts to get a written resolution of all ambiguities and issues in the specifications. Failure to do this can lead to legal disputes and government claims of product substitution which can prevent acceptance of the product system and result in financial penalties.

Developing product systems for government customers requires PSE to do a thorough review and perform internal coordination within the enterprise to prevent it from submitting proposals that are non-compliant because the requirements are not fully understood.

Offered Products

Given an opportunity or perceived opportunity, an enterprise may decide to develop and offer products or services to a broader potential marketplace. The properties of the product or service are often determined through surveying and/or forecasting the potential market penetration. The supplier determines the structure and operation of an appropriate life cycle model for achieving the desired results (Pugh 1990).

Supply Chains and Distribution Channels

The supply of products and services to the owner of a product or service that is acquired or offered at various points during the life cycle is vital to success. It is this wider system-of-interest (WSOI) that is the outsourcing holism that must be treated properly in order to provide successful products or services. A portrayal of supply chain structure is provided in Figure 1 below.

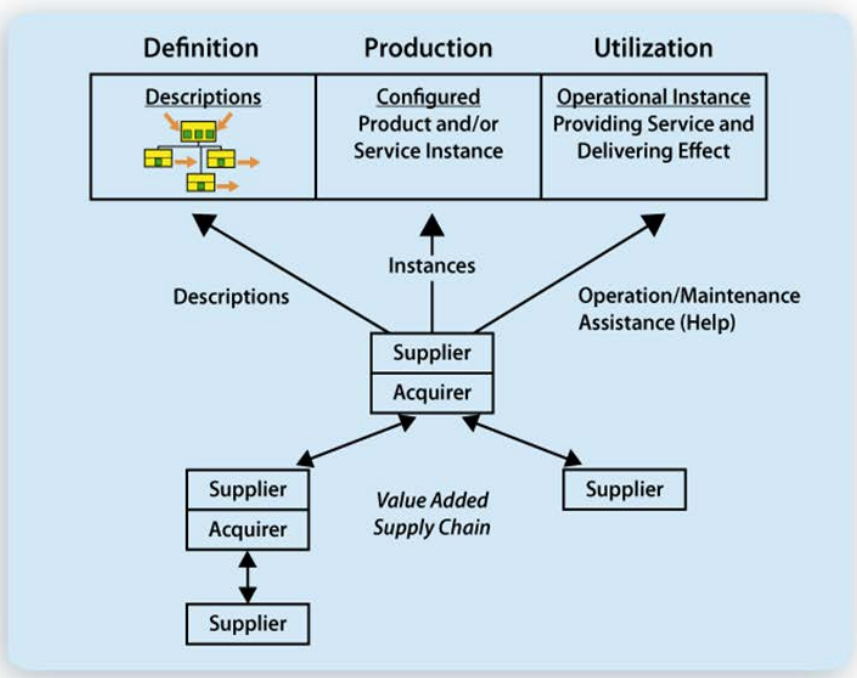

Figure 1. Supply Chain Structure (Lawson 2010). Reprinted with permission of Harold "Bud" Lawson. All other rights are reserved by the copyright owner.

In Figure 1, it is important to note that in an agreement with a supplier, the outsourcing can involve delivering complete system description solutions or portions thereof. For example, a supplier could, given a set of stakeholder requirements developed by the acquirer, develop and supply a system that conforms to the architectural solution. The supplier in turn can be an acquirer of portions of their delivered results by outsourcing to other suppliers.

In regards to production, the outsourcing agreement with a supplier can vary from total production responsibility to merely supplying instances of system elements to be integrated by the acquirer. Once again, these suppliers can be acquirers of portions of their delivery from outsourcing to other suppliers.

In regards to utilization, for non-trivial systems, outsourcing agreements can be made with a supplier to provide for operational services, for example, operating a health care information system. Further agreements with suppliers can involve various forms of logistics aimed at sustaining a system product or service or for supplying assistance in the

form of help desks. Once again, suppliers that agree to provide services related to utilization can be acquirers of the services of other suppliers.

Important to all supply chains is the concept that supplying parties contribute some form of added value to the life cycle of a system-of-interest. The proper management of a supply chain system asset is a vital part of the operations of an enterprise. In fact, the supply chain itself is an enterprise system-of-interest that is composed of acquirers and suppliers as system elements. There is definitely a structure tied together by agreement relationships. Further, the operation of the supply chain results in an emergent behavior. The supply chain system becomes a vital infrastructure asset in the system portfolios of enterprises and forms the basis for extended enterprises.

Similar to a supply chain, the distribution channels for a product system can be a complex web of relationships between the product supplier and various distributors, for example, package delivery companies, warehouses, service depots, wholesale outlets, retail sales establishments, operator training and certification organizations, and so on. The nature of the distribution channels could have a significant impact on the architecture or design of a product system.

PSE may need to include special features in the product design to accommodate for the needs of distribution channel elements, for example, heavy load tie down or lifting brackets, protective shipping packages, retail marketing displays, product brochures, installation manuals, operator certification packages, training materials, and so on. Sometimes it may be necessary to create special versions (or instances) of the product for the training of operators and users for certifying safe or secure operations, for environmental testing and qualification, for product demonstration and user testing, for patent application, for load testing and scalability demonstrations, and for interface fit checking and mass balance certification, to name some examples.

Product Lifecycle and Product Adoption Rates

The life cycle of each product follows the typical incremental development phases shown below (Wasson 2006, 59-65). A particular product to be engineered could be preceded by a previous "model" of that product as shown in the product model life cycle below, and could be superseded later by a newer model of that product. It is worth noting that there is no standard set of life cycle phases. The example below is one of many ways that the phases can be structured.

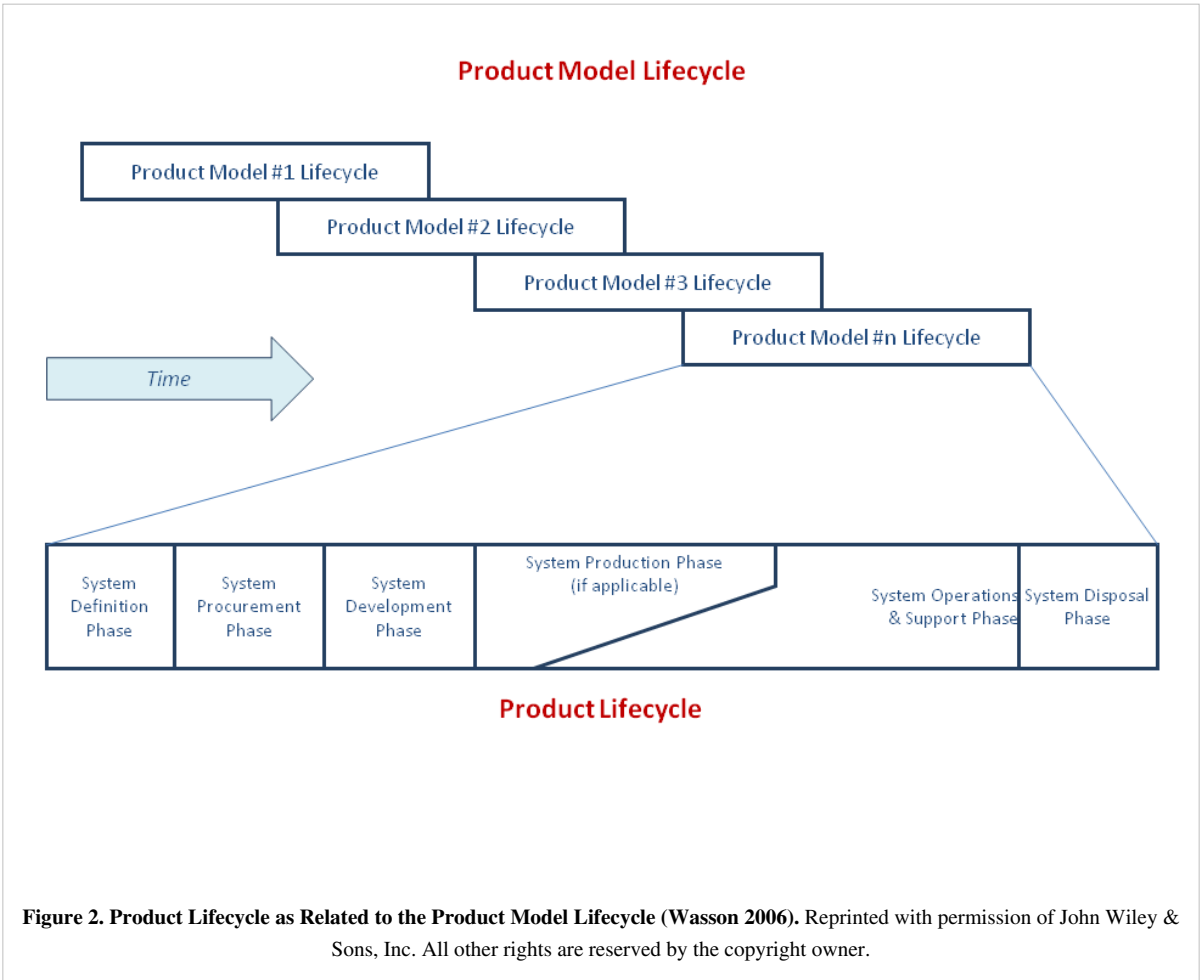

Figure 2. Product Lifecycle as Related to the Product Model Lifecycle (Wasson 2006). Reprinted with permission of John Wiley & Sons, Inc. All other rights are reserved by the copyright owner.

From an industry perspective, managing a product's life cycle involves more than just the engineering aspects:

> *Product lifecycle management (PLM) is the process of managing the entire lifecycle of a product from its conception through design and manufacture to service and disposal. PLM integrates people, data, processes and business systems, and provides a product information backbone for companies and their extended enterprise.* (CIMdata 2012)

There are many PLM tools and services available for facilitating the development and management of complicated product life cycles and especially for product line management (insert link to product line mgmt section here).

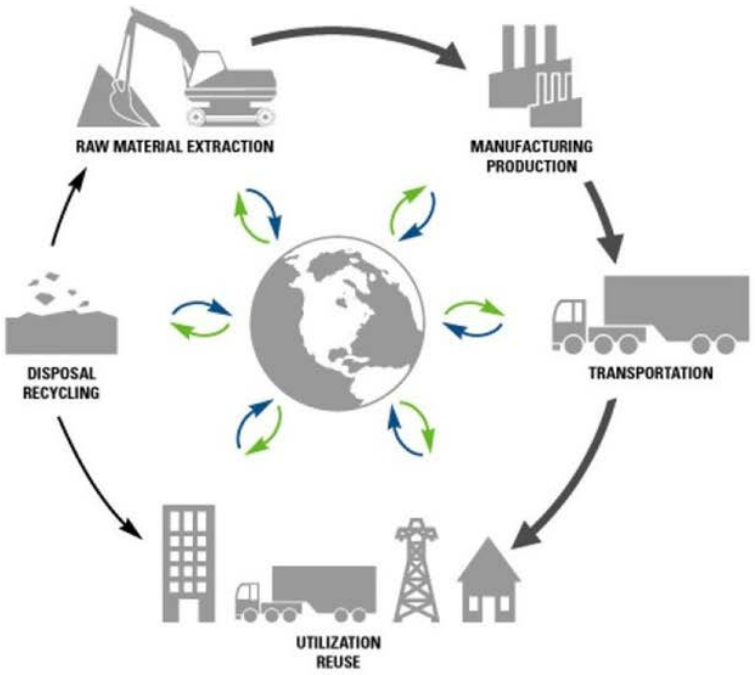

Figure 3. Product Lifecycle from an Industry Perspective. (Source: http://commons.wikimedia.org/wiki/File:Product%E2%80%99s_lifecycle.jpg#filelinks Accessed February 6, 2012. NIST Programs of the Manufacturing Engineering Laboratory, Released by US Federal Government, Public Domain)

The product and product model life cycles are driven by the product adoption rate, illustrated below, that is commonly experienced by most engineered products (Rogers 2003). As products reach market saturation (i.e., on the down slope of the curve below) then there would typically be a new, upgraded version of the product ready for delivery to the marketplace. PSE serves a critical role in determining the best timing for delivery of this new version and the set of features and functions that would be of the greatest value at that time.

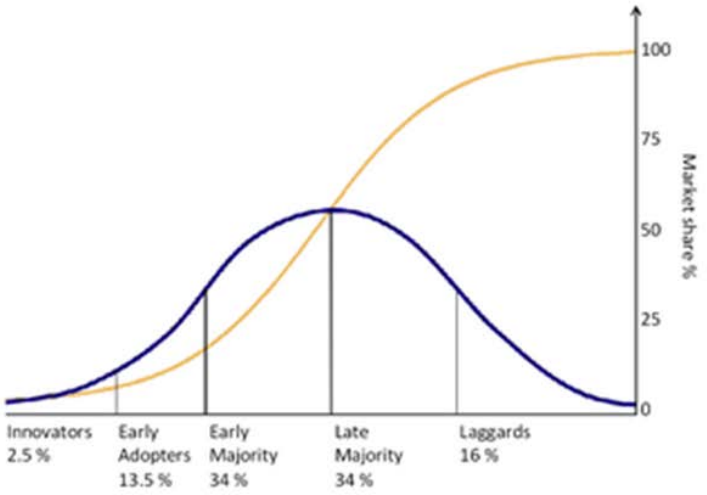

Figure 4. Rogers Innovation Adoption Curve. (Source: http://en.wikipedia.org/wiki/File:Diffusionofideas.PNG Accessed February 6, 2012, Released by Tungsten, Public Domain)

Integrated Product Teams and Integrated Product Development

Product systems as discussed throughout this KA mandate the participation of different disciplines for their success during their entire lifecycle from concept to product disposal or retirement. Rapid technology innovations and market pressures in the mid '90s demanded development process (mostly input-output serial) to shorten their development time and development cost, and to improve product quality to remain competitive. For commercial enterprises, the typical development times of 18-24 months to deploy new products into markets of the '90s have in many cases been reduced to 6-12 months and even 3-6 months for the highly competitive leading edge information technology products.

An initial response to these pressures was concurrent engineering. Concurrent engineering is "... a systematic approach to the integrated, concurrent design of products and their related processes, including manufacturing and support to cause developers, from the outset to consider all elements of the product lifecycle from conception through disposal, including quality, cost, schedule and end user requirements." This definition has evolved into the integrated product development (IPD) as more descriptive of this concurrency to describe the continuous integration of the entire product team, including engineering, manufacturing, test, and support through the life cycle. Later, as the importance of the process was recognized, the terminology was modified to integrated product and process development or IPPD (INCOSE 2012).

The INCOSE *Systems Engineering Handbook* v. 3.2.2 provides a good description of the IPT and IPDT process; the different types of IPDT; the steps in organizing and running an IPDT; good examples of IPDT, particularly for acquired systems; and a good discussion on IPDT pitfalls to avoid. (INCOSE 2012)

IPD/IPPD helps plan, capture, execute, and evaluate programs to help design, test, build, deliver, and support products that satisfy diverse stakeholder requirements. IPD/IPPD outlines the necessary infrastructure needed to deploy, maintain, evaluate and continuously improve processes and tools by aligning people (IPTs) and processes to realize product goals (customer satisfaction). The implementation of Integrated Product Development Processes (IPDP) requires an integrated approach for program planning and generally includes the following: Business Strategy, Program Management and Control, Project Planning, Product Requirements and Architecture Development, Product Design and Development, Production and Deployment, Product Verification and Validation, and Operations and Maintenance Support.

At each development stage, there is a decision gate that helps decide if the IPDP is feasible to enter the next stage of product development. IPD utilizes multi-functional IPTs to optimize the individual product and processes to meet overall cost and performance objectives. IPTs are a cross-functional group of people typically including representatives of all the relevant stakeholders in the project, who are brought together for delivering an integrated product to an external or internal customer using relevant IPDP. The main function of the IPTs is to ensure the business, technical and economical integrity and overall success of the product that is delivered to its eventual customer. IPTs carry out tailored IPDPs and follow relevant SE processes to deliver products that satisfy customer needs, overcomes external constraints, and adheres to the overall program strategy.

In the case of commercial enterprises, product development is tightly coupled with business strategies (short and long term), stakeholder value added measured in terms of return on investments (ROI), market presence/coverage, and other strategies as defined by the business objectives. Thus, product integration teams include strategic planners, business managers, financial managers, market managers, quality assurance managers, customer representatives, and end-users, as well as other disciplines required for acquired products. Phillips (2001), Annachino (2003), and Morse (2007) provide good discussions on this topic.

Role of Architectures, Requirements, and Standards

The architectural properties of a product system are influenced by the concerns of the various stakeholders as indicated in the ISO/IEC 42010 standard (ISO/IEC 2011). The stakeholders have various views that they express based on their specific perspective. These views are vital in establishing requirements and are inputs to those responsible for defining the functions, structures, and relationships needed to achieve the desired product or service.

A number of stakeholders have been identified in the discussions of product systems. It would be possible to identify a set of important stakeholders based on the life cycle thinking provided by the ISO/IEC 15288 standard (2015), for example, one such set could consist of owners, conceivers, developers, producers, users, and maintainers as discussed by Lawson (2010). As mentioned earlier, these stakeholders should cooperate at all stages of the life cycle in specifying requirements, verifying that the requirements are met, and validating that the products produced provide needed capabilities.

In addition to the two standards that have been identified, there are a variety of standards related to specialty aspects of products, such as safety and security, as well as standards that are applicable for project management and life cycle considerations, such as requirements and quality management.

Role of Modeling, Simulation, Prototyping, and Experimentation

Modeling, simulation, prototyping, and experimentation are techniques that have the purpose of improving stakeholder knowledge and shared understanding about aspects of the system to de-risk system development and operation before heavy commitment of time and funds. Examples of this are found below:

- Understanding future needs: “Warfighting experiments are the heart of the Army's warfighting requirements determination process. Progressive and iterative mixes of high fidelity constructive, virtual, and live simulations using real soldiers and units in relevant, tactically competitive scenarios provide Army leaders with future operational capability insights" (US Army 2012),
- Simulation is used to predict and optimize aspects of system performance for which there are good mathematical or logical models before committing the final physical design, and also to verify and validate the system design in scenarios where physical testing is too difficult, dangerous, or expensive, for example, checking the performance envelope of military systems in a wide range of engagement scenarios where test firing thousands of rounds to get statistically valid data is clearly unaffordable, ensuring that the safety features in a nuclear power station will operate correctly in a wide range of stressing scenarios, etc.,
- Prototyping (physical and virtual) is used in a wide variety of ways to check out aspects of system performance, usability, utility, and to validate models and simulations as part of the iterative process of converging on a final design,
- In a manufacturing context, the first units produced are often “prototypes” intended to make sure the production process is working properly before committing to high rate production, and are often not shipped to end users, but used for intensive testing to qualify the design, and
- Simulation is also used extensively for training and marketing purposes. For training, an accurate model of the human machine interface and representation of the operational context allows operators to do most of their training without putting operational hours on the real system enabling them to learn emergency procedures for combat and accident scenarios in a safe and repeatable environment; for example, airline and military pilots now train mainly on simulators. System simulators of various levels of fidelity are used to familiarize customers and end users with the potential characteristics and benefits of the system, available options and trade-offs, and integration issues early in the development and acquisition process.

All of these methods use a variety of physical and mathematical representations of the system and its environment so modeling is an enabler for simulation, prototyping, and experimentation.

Increasing Role of Software in Product Functionality

An important trend in commercial products is the increasing importance of software in an increasingly wide range of products. Everything from phones, cameras, cars, test gear, and medical equipment now has essential functionality implemented in software. Software has had an increasing role in providing the desired functionality in many products. The embedding of software in many types of products accounts for increasing portions of product functionality. In tangible products such as cars, software helps improve functionality and usability (cruise control, climate control, etc.). In intangible products such as insurance, software helps in improving operational efficiency, data accessibility, etc.

The movement toward the internet of “things” where sensing and activating functions are incorporated is now starting to permeate. The use of various software products in proving service is also described in the Service Systems Engineering article.

Recent advancements in IT and software have assisted in their increased use in PSE. Although software development is already a very complex field, the role of software in the development and functionality of products is growing larger each day.

There is a need to broaden the horizons of software engineers to think of problem solving not only in software terms, but also using the systems thinking approach. For this purpose, software engineers need to be able to think critically about the problem and also the possible solutions to the problem or opportunity and its implication for business objectives.

Product Integration and Interface Control

Integration is "the set of activities that bring together smaller units of a system into larger units" (Eisner 2008). Products may consist of several systems, subsystems, assemblies, parts, etc., which have to work together as a whole to deliver the offered product's functionalities at specified performance levels in the intended operations environment. Product integration entails not only the working together of hardware and software components, but also the organization, processes, people, facilities, and the resources for the manufacturing, distribution, maintenance, customer support, sales channels, etc. Grady (2010) groups the above information into three fundamental integration components: functional organization, product integration, and process integration.

PSE plays an important role to ensure well defined interfaces, interactions, relationships, information exchange, and processes requirements between product components. These requirements are baseline, documented, traced, verified, and validated for the end-to-end Product integration and to maintain and ensure product offering integrity during its life cycle. The systems engineering hierarchical decomposition level allows requirement definition and allocations at different levels of abstraction to define the building blocks of the product architecture; these building blocks are assigned to integrated product development teams (IPDTs) for detailed design and development. The IPDTs or the systems engineering integration team (SEIT) must interact with all involved players to generate appropriate architectural block specifications at the lower tier of development for a product's architectural configuration and configuration tracking. As the building blocks are put together, interface requirements, information exchange, and interaction and relationships among entities are verified against the baseline. Once a configuration item has been built and tested against the baseline, test and verification at higher levels are conducted to obtain the final product configuration; the final product configuration can only be changed by a formal approval from a configuration control board (CCB). Note: the acronym CCB is often used to mean the change control board that, in addition to configuration control, makes decisions of any aspect of a project or an enterprise.

Interface agreements, specifications, and interface designs are usually documented through the interface control documents (ICD) and the interface design descriptions (IDD); in some instances, depending on the complexity of the product and the type of internal and/or external interfaces, an interface control working group (ICWG) is created to analyze and baseline changes to an interface for further recommendation to the CCB.

A configuration item (CI) may be hardware (HWCI), software (SWCI), firmware, subsystems, assemblies, non-development items, commercial off-the-shelf (COTS) items, acquirer furnished equipment, and/or processes. Please see Wasson (2006), Grady (2006), and INCOSE *SE Handbook* v. 3.2.2 for a more detailed description of configuration and interface control.

A product may experience hundreds of changes during its life cycle due to new product releases/enhancements, repair/replacement of parts, upgrades/updates in operating systems, computer infrastructure, software modules, organizational changes, changes in processes and/or methods and procedures, etc. Thus, strong mechanisms for bookkeeping and activity control need to be in place to identify, control, audit, account and trace interfaces, interactions, and relationships between entities that are required to maintain product configuration status (Eisner 2008). The product configuration and CI's are then controlled through the configuration management process.

Configuration Management and Risk Management

Configuration management (CM) deals with the identification, control, auditing, status accounting, and traceability aspects of the product, and broadly covers the book-keeping and control activities of the systems engineering process (Eisner 2001). Any product configuration changes to the baseline (configuration item, operational baseline, functional baseline, behavior baseline) or product baseline are submitted to a configuration control board (CCB) through an engineering change request (ECR) and/or a configuration change request (CCR). The CCB then analyzes the request to understand CI impacts and the feasibility (time and cost) of authorization or rejection of change request(s). The lack of proper control and tracking of CI and product baselines may result in a loss of features, functionality, data, interfaces, etc., leading to backtracking and CI version losses which may affect the offered product. All approved changes will have to be baselined, documented, and tested for backward compatibility and to ensure compliance with the integrated product functionality. Thus, successful implementation and life cycle management of the product mandates a highly disciplined CM process that maintains proper control over the product and its components. Please see the INCOSE *Systems Engineering Handbook* v. 3.2.2 (2012) for a detailed description of the CM Process.

Risk management deals with the identification, assessment, and prioritization of technical, cost, schedule, and programmatic risks in any system. Almost all engineered systems are designed, constructed, and operated under some level of risks and uncertainty while achieving multiple, and often conflicting, objectives. As greater complexities and new technologies are introduced in modern systems, the potential of risks have significantly increased. Thus, the overall managerial decision-making process should involve an extensive cost-benefit analysis of all identified, qualified, and evaluated risks (Haimes 2008). Risk management involves the coordinated and most cost-effective application of resources to minimize, monitor, and control the probability and/or impact of all identified risks within the systems engineering process. The risk management process requires the involvement of several disciplines and encompasses empirical, quantitative, and normative judgmental aspects of decision-making. Furthermore, risk assessment and management should be integrated and incorporated within the broader holistic approach so technology management can help align the risk management requirements to the overall systems engineering requirements. Thus, the inclusion of a well defined risk management plan that deals with the analysis of risks, within the systems engineering master plan is vital for the long term and sustained success of any system (Blanchard and Fabrycky 2011).

Product Systems Engineering Special Activities

- Lead Author:
- Ricardo Pineda

-

Product systems engineering has activities that are unique to products. This article discusses many of them.

The "Product Systems Engineering" knowledge area is graciously sponsored by PPI.

Readiness Level Assessments

As a new system is developed, it is essential to verify and validate that the developed system is mature enough to be released as an operational product or service. Technology readiness assessments (TRA) are established tools used to qualify technology development and help make investment decisions within complex development programs in order to deploy systems or elements of technology to an end user in a timely fashion.

This notion of maturity was formalized by the US National Aeronautics and Space Administration (NASA) (Mankins 1995) and later modified for use by the Department of Defense (DoD), the Air Force Research Laboratory (AFRL), and the US Department of Energy (DoE), as well as a growing number of non-governmental organizations. Technology readiness levels (TRL) are a metric developed to summarize the degree of maturity of a technology. The original NASA TRL scale has nine different levels from the *basic principles observed and reported* (TRL 1) to *actual systems "flight proven" through successful mission operations* (TRL 9). The TRL scale utilized by the DoD is portrayed in Table 1.

Table 1. Technology Readiness Levels for Assessing Critical Technologies (Mankins 1995). Released by the Advanced Concept Office, Office of Space Access and Technology, NASA.

Technology Readiness Level	1. Basic principles observed and reported.	2. Technology concept and/or application formulated.	3. An analytical and experimental critical function and/or characteristic proof of concept.	4. Component validation in laboratory environment.	5. Component validation in relevant environment.	6. Prototype demonstration in a relevant environment.	7. Prototype demonstration in an operational environment.	8. System qualified through test and demonstration.	9. System proven through successful mission operations.	Actual application of the technology in its final form and under mission conditions, such as those encountered in operational test and evaluation.

The utilization of TRLs has an impact on the structure and operation of life cycles as described in Part 3; they allow better management and control of risks inherent with technology, as well as better control of costs and the schedule of program development. However, TRLs do not provide an assessment of the programmatic influence on a TRL, technology criticality and priority, software aging and readiness context, as pointed out by Smith (2005). While TRLs have proven to be useful in evaluating a technology's performance, as demonstrated in the laboratory or in a test environment, they do not inform one whether or not the technology product can actually be produced in an affordable manner. The concept of manufacturing readiness levels (MRL) has been incorporated to expand the TRL idea so that it can incorporate producibility concerns. The MRL approach addresses questions such as the level of technology reproducibility, the cost of production, and technology manufacturing production environment early in the development phase (GAO 2003, DoD 2011).

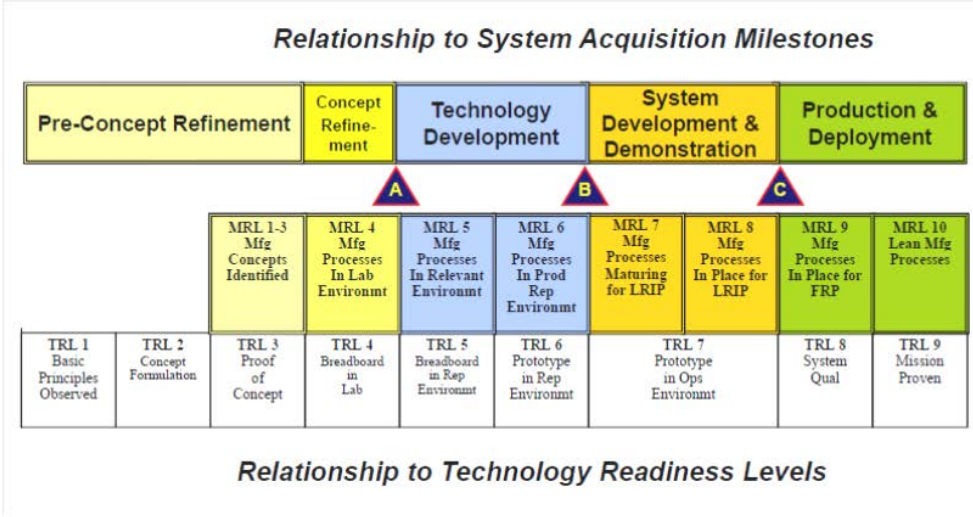

Figure 1. Technology Readiness Levels and Their Relationship to System Acquisition Milestones (Morgan 2008). Released by the Manufacturing Technology Division of the United States Air Force.

Readiness levels are an active research area within academia and government agencies in regards to the integration of technology components into complex systems (integration readiness levels (IRLs)) to address interface maturity among existing and maturing technology developments. TRLs apply to the critical enabling technologies, which are usually embodied at the subsystem, assembly level, or system component level. Systems readiness levels (SRL) are used when going from individual technologies to the whole system. The SRL model is a function of the individual TRLs in a system and their subsequent integration points with other technologies, the IRL (Sauser 2006).

Another maturity aspect is related to the provisioning of products that are readily available and referred to as commercial off-the-shelf (COTS). Such products, be they hardware, software, or a mixture of both, have hopefully achieved the degree of maturity so that those acquiring them can rely upon their operational properties and that the documentation of the COTS products is sufficient to provide the proper guidance in their use.

The PSE should realize that the TRL assessment for COTS changes dramatically if the operational environment or other requirements are imposed that exceed the design limits of the COTS product (e.g., operations at very high or very cold temperatures, high shock, or vibration levels).

Product Certification

Product certifications are both domain and product specific, and typically relate to human safety and health, the need to meet a specific government regulation, or are required by underwriters for insurance purposes. Certifications are performed by a third party (independent of the developer) who provides a guarantee of the quality, safety, and reliability of the product to the customer or user.

The INCOSE *SE Handbook* defines product certification as "the process of certifying that a certain product has passed performance or quality assurance tests or qualification requirements stipulated in regulations such as a building code or nationally accredited test standards, or that it complies with a set of regulations governing quality or minimum performance requirements." (INCOSE 2012)

The INCOSE *SE Handbook* also defines four methods for verification: inspection, analysis, demonstration, and testing (INCOSE 2012). In addition, it defines certification as a fifth verification method, which is defined as verification against legal or industrial standards by an outside authority without direction to that authority as to how the requirements are to be verified. For example, electronic devices require a CE certification in Europe, and a UL certification in the US and Canada (INCOSE 2012).

The best known certification is the airworthiness certification, which relates to the safety of flight for aircraft. In the US, the test for this certification is performed by the Federal Aviation Administration (FAA). Government certifications are also common in the medical systems field where the Federal Drug Administration (FDA) is the primary certification agency. Some certifications are based on standards defined by technical societies, such as the American Society of Mechanical Engineers (ASME). The combination of the technical standards and a certification allows product developers to perform certifications that meet government standards without having the government directly involved in the process.

There are equivalent government organizations in other countries and for other regulated areas, such as communications, building safety, nuclear systems, transportation systems to include ships, trains and automobiles, environmental impact, and energy use. Systems engineers must be aware of the certifications that are required for the domain and product being developed. Certification agencies must be involved early in the development effort to ensure the necessary certifications are included in the system requirements, the system development plan, and the funding provided to accomplish the development. When system changes and upgrades are necessary, the systems engineers must determine if product re-certification is necessary and include it in the plans and funding for the system upgrade.

Enabling Product Certifications

There may be other certifications for enabling products that must be considered and appreciated by PSE, such as an operator certification of airplane pilots to ensure flight safety, and certification of nuclear plant operators to ensure prevention or mitigation of nuclear radiation effects. An example of this is shown in the certification program by the North American Electric Reliability Corporation (NERC):

> *In support of NERC's mission, the System Operator Certification Program's mission is to ensure that employers have a workforce of system operators that meet minimum qualifications. These minimum qualifications are set through internationally recognized processes and procedures for agencies that certify persons. The Certification Program promotes excellence in the area of system operator performance and encourages system operators to be inquisitive and informed.* (NERC 2012)

Production qualification testing (PQT) is another type of certification which DAU (2005) describes as:

> *A technical test completed prior to the full-rate production (FRP) decision to ensure the effectiveness of the manufacturing process, equipment, and procedures. This testing also serves the purpose of providing data for the independent evaluation required for materiel release so that the evaluator can address the adequacy of the materiel with respect to the stated requirements. These tests are conducted*

> *on a number of samples taken at random from the first production lot, and are repeated if the process or design is changed significantly and when a second or alternative source is brought online.*

Security certification and accreditation (C&A) is often required for the deployment of computing and networking equipment in a classified environment. Facility certification may be required to ensure that a building housing the equipment can provide the proper environment for safe and efficient operation of the equipment. High-altitude electromagnetic pulse (HEMP) certification may be required to ensure that a building and its equipment can withstand the effects of HEMP from nuclear weapons. A similar type of certification to HEMP is TEMPEST testing to ensure that sensitive electronic emissions are not allowed to leave high security facilities. TEMPEST is a code name referring to investigations and studies of compromising emission, and is not an acronym.

Technology Planning and Insertion

Technology planning can be an enterprise function or a program function. Technology planning as an enterprise function typically occurs on an annual basis to determine the funding necessary for independent research and development in the coming year. Technology planning as a program function occurs early in the program and often continues throughout the life of the system. The design of the product system is highly dependent on the availability of technologies that have acceptable risks and that meet the customer's cost, schedule, and performance requirements. These critical technologies will only be available when necessary if the systems engineers perform concept designs, technology assessments, and trade studies that define the critical technologies and the capabilities necessary before the system development activities that will use the critical technologies begin.

The MITRE *Systems Engineering Guide* (MITRE 2011) provides the following definition for technology planning:

> *Technology Planning is the process of planning the technical evolution of a program or system to achieve its future vision or end-state. Technology planning may include desired customer outcomes, technology forecasting and schedule projections, technology maturation requirements and planning, and technology insertion points. The goal is a defined technical end-state enabled by technology insertion over time.*

Systems engineers who participate in technical planning must understand the future vision and system requirements, and relate these to the current and expected future technologies that can be applied to the system design during current development stages, as well as for potential future upgrades to the system. To do this, systems engineers must acquire and maintain knowledge of the existing and developing technology in their design domain. The systems engineer will also provide the essential connection between the system user and research communities to provide alignment between the technology developers and the system designers.

Technology planning and insertion usually requires that the systems engineer perform technology readiness assessments that rate the maturity levels and the risks associated with the planned technologies. Immature, risky technologies require risk reduction activities that include prototyping and product development and test activities that provide quantification of the capabilities and risks. The risk reduction activities provide the data necessary to assess and update the design to reduce its risk.

Product Road Mapping and Release Planning

Product road maps provide an outline that shows when products are scheduled for release and include an overview of the product's primary and secondary features. Both internal and external product road maps should be created. The form of the road map will depend on the development methodology being used. Waterfall, iterative, and spiral development models result in different road maps and release plans. The systems engineer must be an integral member of the team that creates road maps. Requirements should be mapped onto each of the planned releases. Test plans must be adapted to the development model and the release plans.

Product road maps should be aligned with the technology road maps that are applicable to the product. Technology maturity should be accomplished before the technologies are included in the product development plans and the road map for the product release that includes those technologies.

Product road maps are essential for software intensive systems that have many releases of software and capability upgrades. The identification of the requirements, the test plans, and the features provided for each release are an essential driver of the product development process. Clear definition of these items can make the difference between delivering the capabilities the customer is looking for and will support, or a product that fails to meet the needs of the customer and is abandoned.

Intellectual Property Management

Systems engineers must also manage intellectual property as part of their job. Existing systems engineering literature rarely covers this topic. However, there are many textbooks and management related literature that provide additional information, such as “Intellectual Property Rights for Engineers” (Irish 2005). Intellectual property may be considered as *intangible output of the rational thought process that has some intellectual or informational value and is normally protected via using copyrights, patents, and/or trade secrets* (Irish 2005). Listed below are some of the more important intellectual property types with brief explanations:

- Proprietary Information: Any information which gives a company (or enterprise) an advantage over its competitors is usually proprietary.
- Patents: A patent is the principle mechanism for protecting rights for an invention or discovery. In exchange for a full disclosure of how to practice it, the issuing government will grant the right to exclude others from practicing the invention for a limited amount of time, usually 15 to 20 years (in the US, a patent usually lasts for 17 years from the date of issue).
- Design Patents: In some countries, these are referred to by the more appropriate term *design registrations* or some other name. They protect rights in ornamental designs, provided the designs are new and inventive, i.e., *non-obvious* at the time they are made. In the US, the maximum length of a design patent is 14 years.
- Trademarks: A trademark identifies the source of origin for goods in commerce, and is not stronger than the actual use to which it has been put to and the diligence with which it has been protected from infringement, encroachment, or dilution. Under some circumstances, a trademark may be registered with governmental agencies. Among a company's most valuable assets is the corporate name, which also is the company's primary trademark.
- Copyrights: A claim of copyright protects such works as writings, musical compositions, and works of art from being copied by others, i.e., from plagiarism. A notice of claim of copyright must be made in the manner prescribed by law at the time of a protected work’s first publication.

Parts, Materials, and Process Management

The consequences of mission failure or an inability to deploy the system on time due to parts, materials, and process (PM&P) issues needs to be clearly understood by the systems engineer since these elements are fundamental to the overall mission reliability and program success. PM&P management is especially important in harsh environments (like outer space and underwater) and in situations where system failure can have catastrophic impacts on public safety (like nuclear power, bridges and tunnels, and chemical processing plants).

Generally, original equipment manufacturers (OEMs) engaged in the design and fabrication of electronic systems have a documented policy that deals with PM&P, sometimes in the form of a PM&P Management Manual. The elements of a PM&P control program include things such as

- PM&P requirements that apply to a system;
- the generation number of a program or project approved parts list (PAPL);

- the appointment of a PM&P control board (PMPCB);
- the development of a part stress derating policy and a part parameter derating policy for end of life use; and
- a definition of the minimum qualifications, quality controls, and screening requirements for parts.

PM&P management guidance is provided by MIL-HDBK-512 (DoD 2001) and ANSI/AIAA R-100 (2001), which identify the overall management process elements of a PM&P program. Additional issues to be addressed by PM&P include the following: hazardous materials, rare earth elements, conflict materials, and counterfeit materials.
